In Novorossiisk, on March 30th last, there were 1159 cases of typhus fever in hospital, and on April 6th this figure had increased to 1336. The case mortality, however, was said to be still low. During the summer months the epidemic, as usual, declined. In the late summer and autumn, however, the disease was still present in the Crimea; thus in the week ending August 15th (28th), there were 10 fresh cases in the Russian garrisons of the Crimea; and on August 25th (Sept. 7th) 53 cases remained in the various hospitals; of these, 33 were in the Theodosia hospitals. Since the Crimea fell into the hands of the Bolsheviks, no information has been received as to the presence of disease or as to the other conditions of life prevailing there. With the exodus of some 150,000 refugees from the Crimea to Constantinople, typhus and other diseases have, as already stated, been imported to the Turkish capital. The special prevalence of relapsing fever amongst them has been referred to above, and mention may here be made (as a postscript to the earlier paper upon cholera) of an outbreak of cholera in a Russian refugee camp in the neighbourhood of Constantinople. In this camp, situated at Chilinghirkoui, not far from the famous lines of Chataldja and some 20 miles from the capital, some 10,000 refugees were interned. Cholera appeared amongst them in the night of Dec. 9th–10th. In all some 88 cases and 47 deaths occurred. Energetic measures, however, were put in force at the earliest possible moment, and the outbreak came to an end on Dec. 19th, since when no cases have been reported. Four other cases were seen in a French hospital in the town of Constantinople in the first few days of December. All four patients had been in hospital for some time for other diseases. Only one was a Russian, the others being a Greek man, a Greek woman, and a Syrian woman. Neither in these cases nor in those at Chilinghirkoui could the source of infection be traced, and it is believed to have been due to some germ-carrier or carriers from the Crimea. It is, however, to be noted that, so far as our information goes, cholera had ceased to be present in the Crimea some time in October.

Constantinople, Dec. 30th, 1920.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

Sanatorium Benefit in Scotland.

THERE appears to be some misunderstanding of the position of sanatorium benefit in Scotland. In England sanatorium benefit will not cease until May 1st, to be included among the benefits conferred upon insured persons by Part I. of the National Insurance Act, 1911; but in Scotland this termination has actually taken place, and as from the first of the present month the local sanitary authorities have been required to make arrangements for the treatment of tuberculosis in insured persons. Special arrangements have been made to ensure that there shall be no break in the continuity of treatment resulting from this transfer, and a special scheme has been devised for the treatment of ex-Service men suffering from tuberculosis. The local authorities are to receive in respect of the treatment of insured persons suffering from tuberculosis an Exchequer Grant, which may be taken broadly as representing the amount that has been available to local Insurance Committees for institutional treatment. In respect of ex-Service men, they will obtain reimbursement of the entire cost and will also receive payment for the services of their tuberculosis officers.

Cameron Prize Lecture.

On Jan. 14th Sir Robert Jones, Inspector of Military Orthopædics, who last year was awarded the Cameron Prize in Therapeutics, delivered a lecture at Edinburgh University on the Necessity of Orthopædic Training and its Relation to the Prevention and Cure of Cripples. He emphasised the need for education of the student in orthopædic principles. Deformities which occurred early were mainly the result of tuberculosis, rickets, infantile paralysis, or were of congenital origin. Many of them might be prevented, and practically all of them might be corrected. They had to trust to the practitioner for early diagnosis, and he should at least know the possibilities of modern treatment. Nearly all crippling deformities of children and adults were included in "orthopædic" surgery, as well as a large proportion of war injuries. It was in consequence of the ever-increasing number of deformities that orthopædic centres were started during the war. They commenced with 250 beds in Liverpool, and eventually throughout the kingdom 20,000 beds were set apart. Specially qualified staffs were put in charge, and the patients were allowed a longer period of hospital treatment than in the general military hospitals. For psychological and reconstructive purposes curative workshops were introduced. The advantages of these methods had been very marked. Training in the treatment of fractures required to be more general than at present, and a thorough training in the simplest types of appliances and the principles governing their application would spare humanity numberless deformities. Appliances should be of the simplest kind. In every hospital there should be a fracture ward, and the chief should be both interested and competent. The treatment of fractures in this country was at present a sadly neglected art, and it was only recently and as a result of the war that the need for orthopædic instruction had become recognised. A thorough training in general surgery was an essential preliminary. In certain hospitals the orthopædic department was too often a mere out-patient clinic. It was better to have no orthopædic department than to make it a pretence. He welcomed the institution of an orthopædic lectureship in Edinburgh, and would like to see this new department add lustre to the glorious traditions of the University.

A Glasgow Society for Psychical Research.

A society has been formed in Glasgow for scientific research work into psychic phenomena. Its members are committed to no definite opinions on the subject of psychic phenomena, and their work is to be purely that of investigation. The medical office-bearers of the society, of which Mr. A. J. Balfour is president, include Dr. A. K. Chalmers and Dr. L. R. Oswald, vice-presidents. The honorary secretary is Miss Margaret H. Irwin, 58, Renfield-street, Glasgow.

The John Farquhar Thomson Lectureship.

The first of this year's series of lectures on the Structure and Functions of the Human Body was given in the Anatomy Theatre of Marischal College, Aberdeen, on Jan. 15th, by Dr. R. W. Reid, professor of anatomy at the University. The lectureship was founded by the late Mr. John Thomson, of the University Press, in memory of his son, formerly a distinguished student of the University. The lectures are open to the public, and are intended chiefly for young persons, to instruct them in the care of the body, its healthy development, and the prevention of its abuse by intemperance. The course consists of six lectures, which are to be delivered each winter, when a different lecturer will be chosen.

Infant Mortality in Inverness-shire.

The report of the medical officer of health for Inverness-shire for the year 1919 gives infantile mortality statistics for the last six years for each district:—

	Births.	Deaths under 1 year.	Infantile mortality.
Inverness...	790	... 65 ...	82
Aird	762	... 45 ...	56
Badenoch ..	619	... 42 ...	67
Lochaber...	558	... 22 ...	39
Skye	1266	... 69 ...	54
North Uist	317	... 12 ...	37
Harris ...	563	... 35 ...	62
South Uist and Barra	809	... 54 ...	66

The rate is thus lowest in North Uist with 37, followed by Lochaber. The infantile mortality rate for the county is 60.

The late Dr. J. W. Simpson.

On Jan. 11th the death took place at Edinburgh from pneumonia of Dr. J. W. Simpson. Dr. Simpson was best known professionally for his work on children's diseases, on which subject he had made numerous contributions to medical literature. His work as physician to the Royal Hospital for Sick Children and his ability as a teacher were recognised by students and graduates alike as being of an exceptional high standard. From 1893 to 1899 Dr. Simpson was well known as one of Scotland's most prominent Rugby internationalists, playing altogether in 13 internationals. He graduated M.B., C.M. at Edinburgh in 1896 and M.D. in 1906. He was a Fellow of the Royal College of Physicians of Edinburgh. For his sterling qualities Dr. Simpson was greatly esteemed and beloved by all who knew him, and his early death has caused widespread sorrow.

Jan. 17th.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Health Insurance and the Medical Profession.

THE possibility of a forthcoming Health Insurance Bill before the French Parliament was recorded in the minutes of the last general meeting of the "Union des Syndicats Médicaux," which was held on the 4th and 5th of last month. The committee of the "Syndicat des Médecins de la Seine" has pointed out that such a medical act would completely transform the practice of medicine in France and has urged all practitioners to take an active interest in the question before the Bill is actually discussed in Parliament. The abovementioned committee has appointed a subcommittee whose members are: MM. Ferry, Gascuel, Hartmann, Lafontaine, Le Fur, Rinuy, and Rouyer. Mons. Rinuy has been appointed secretary. This body will deal with all matters concerning health insurance, and the results of its investigations will be regularly published in the *Bulletin*.

Rates and Payment of Pensions in Alsace.

According to Article 62 of the Versailles Peace Treaty, Germany is to pay in marks the pensions allotted to Alsatians who fought in her army during the war. Alsatians who fought in the ranks of the French army benefit from the French Pension Act, March 31st, 1919. Mons. Daussat, médecin-chef of the medical board for Strasbourg, has given recently a detailed account of the German Pension Act of May 14th, 1920, and has pointed out that on many points it is in accordance with the spirit of the French law. He mentions that owing to the disadvantageous rate of exchange of the mark the French Government have decided to make up the difference and to secure to the disabled Alsatians who served in the Germany army pensions approximately the same as those paid to pensioned ex-Service men in France.

Prophylaxis of Malaria.

Mons. Marcel Léger, Director of the Medical Service in French Guiana, has published a report on various matters concerning malaria in this French colony: "L'Endémie Palustre à la Guyane Française" (*Annales de Médecine et de Pharmacie Coloniale*, numéro exceptionel, 1920). Mons. Léger concludes by referring to the results attributable to prophylactic measures; according to statistics taken in prisons a marked decrease in the occurrence of malaria amongst convicts has been recorded since 1900. Moreover, since 1909 the number of patients suffering from malaria who have been admitted to hospitals has been gradually diminishing, leaving out of consideration an epidemic in the course of the years 1917 and 1918.

Jan. 15th.

ROYAL SOCIETY.—At the next meeting, on Jan. 27th, at 4.30 P.M., the following papers will be read: Mr. K. Sassa and Professor C. S. Sherrington, P.R.S., on the Myogram of the Flexor-reflex Evolved by a Single Break-shock. Sir Almroth Wright, F.R.S., on "Interaction" Between Albuminous Substances and Saline Solutions. Professor S. Russ, Dr. Helen Chambers, and Miss Gladwys M. Scott, on the Local and Generalised Action of Radium and X Rays upon Tumour Growth, communicated by Sir Walter Fletcher, F.R.S.

THE HYGIENE OF INDUSTRY.

Fatigue and Efficiency in the Iron and Steel Industry.

AN interesting study has been issued by the Industrial Fatigue Research Board relating to the iron and steel industry.[1] The inquiry upon which it is based was set on foot to establish a comparison between the 12-hour shift system of working and the 8-hour shift system, which commenced in February, 1919. The comparison was difficult to make, for Dr. H. M. Vernon, the investigator to the Board, who writes the report, found himself face to face with an intricate problem in attempting to estimate accurately the effect of work upon those employed. He describes clearly the processes of producing pig-iron, of converting it into steel by different methods, and of rolling steel. Readers unfamiliar with the industry will be struck by the complexity of the processes, by the variety of methods in vogue in different parts of the country, and by the difficulties to be surmounted in separating the human from the trade technical factors.

Unnecessary Labour is the Rule.

Dr. Vernon is not a technical metallurgist, but nevertheless his survey of the industry enables him to point to curious anomalies in working methods; indeed, we find ourselves wondering at the extent to which this key industry seems in this country to be behindhand rather than marvelling at splendours of metal smelting. Much of the work, on account of the physical labour involved, together with exposure to great heat and varying weather conditions, belongs to the heaviest which men have to undertake; but the picture drawn for us is that of human intelligence busied with the extraction of metal, absorbed in wrestling with metallurgical problems, with no time devoted to the working of the human beings who guide the operations—those beings who after all are part of the community needing the metal. Often, as in the case of blast furnaces, unnecessary labour seems to be the rule rather than the exception; here "the efficiency of mechanical charging is four to eight times greater than that of hand charging," yet in Scotland no furnaces were found mechanically charged, in Yorkshire only 21 per cent., in South Wales 26 per cent., and in Lincolnshire 32 per cent.; in all, only 18 per cent. out of 146 furnaces inspected. The men lose an undue proportion of time for sickness, and Dr. Vernon concludes that "a reduction of the 12-hour shifts to 8-hour shifts will lead to an improvement of time-keeping and thereby increase the efficiency with which the blast furnaces are run." Equally important would appear to be the introduction of labour-saving devices. The same story is told regarding open-hearth steel furnaces; here a steel melter transferred from a 30-ton hand-charged furnace to a 70-ton machine-charged furnace declared the latter by comparison to be almost child's play. In terms of man-power, machine-charged furnaces were about five times more effective than hand-charged ones. "There can be little doubt, therefore, that all hand-charged furnaces ought to be scrapped with the utmost expedition and replaced by machine-charged furnaces."

Efficiency and the Health of Workers.

Other factors adversely influencing production are also pointed out, such as the use for conversion into steel of metal still hot from blast furnaces instead of first allowing it to cool and then reheating it; and also imperfect balance in the plant leading to later processes being frequently delayed for lack of material—"the consistency of the delays," writes Dr. Vernon, "is very striking." He finally concludes that probably—

> "if all the iron and steel works in the country adopted the most efficient methods they could, on an average, improve their output by something between 50 and 100 per cent. In other words, they could enable their employees to earn more in 8-hour shifts than they had previously done in 12-hour

---

[1] Fatigue and Efficiency in the Iron and Steel Industry. H. M. Vernon. Industrial Fatigue Research Board. Report No. 5. Pp. 99. H.M. Stationery Office. 1920. 3s.

shifts. . ... It is suggested that a technical inquiry into these proposed changes by a competent body of practical men is well worth consideration."

We agree, and venture to hope that the industry will either refute this accusation of partial inefficiency or remedy the condition. The matter would be foreign to our sphere of thought if the health of the workers were not intimately concerned. But Dr. Vernon and Mr. E. A. Rusher, after careful statistical inquiry into the morbidity and mortality experienced, indicate how activity is curtailed by sickness and life shortened by early demise. Thus we read:—

> "The steel melters and pitmen lost 23 per cent. more time than the average, the puddlers 20 per cent. more, the tinplate men 12 per cent. more. Almost all of these men frequently work at high temperatures, whilst the engine- and cranemen and the other workers (largely labourers), who usually work at ordinary temperatures and on less heavy work, showed 8 or 9 per cent. less sickness than the average. The excess of sickness shown by the puddlers was due entirely to rheumatism and respiratory diseases."

And again, steel workers—

> "showed 102 per cent. greater mortality from respiratory diseases, but 48 per cent. smaller mortality from tuberculosis (mostly phthisis). The steel-melters had a 20 per cent. greater mortality than all males, but the other men working at high temperatures and the engine- and cranemen had a smaller mortality. It is probable that all the records yield too low an estimate of the death-rate owing to withdrawals of some of the less vigorous men. The blast-furnace men had a considerably higher mortality than the steel-workers, presumably because of their great exposure to the weather."

Relation between Sickness and Mortality Returns.

Considerable interest attaches to this investigation since we have here the first attempt, so far as we know, made to show a definite association between the sickness experienced by any group of persons and their causes of death; here sickness from respiratory diseases goes hand-in-hand with mortality from these diseases, but no relation is stated between rheumatism and any form of death. Again, definite evidence is given as to the conditions associated with these forms of illness; thus, after stating the evidence, the authors draw the deduction that probably—

> "excess of sickness from rheumatism and respiratory diseases was due to exposure to weather; ...... work at normal temperatures in the open is more likely to cause rheumatism and respiratory disease than work at high temperatures, but under cover."

Investigations carried out by the Fatigue Board on these lines cannot fail to throw light not merely upon the occurrence of human fatigue, but also upon the causation of sickness of different kinds, and upon the relation between different forms of ill-health and different causes of death, matters concerning which there is to-day a great deal of a priori deduction to one pennyworth of fact.

Not less interesting than the high mortality from respiratory diseases is the low mortality from phthisis. Here is evidence, just as among coal-miners, of phthisis and respiratory diseases not moving together, while certain other occupations, such as printing, tailoring, and boot-making, provide instances of phthisis in excess with respiratory diseases below normal. In other words, statistics do not favour the idea that phthisis develops from bronchitis and pneumonia.

We recommend this report to all interested in industrial medicine: it is one of considerable importance. Dr. Vernon may be congratulated upon the way in which he has extracted valuable information from what must have at first appeared unpromising material.

MEDICO-LEGAL SOCIETY.—The meeting announced for Jan. 18th was postponed and will take place at 11, Chandos-street, Cavendish-square, London, W., on Jan. 28th at 8.30 P.M., when Dr. H. Gibson Sutherland will read a paper.

HUNTERIAN SOCIETY.—The annual dinner will be held on Wednesday, Feb. 2nd, at the Trocadero Restaurant, at 7 P.M. for 7.30. Dr. A. C. Jordan, President, in the chair. Ladies will be invited. Tickets, price 16s. 6d., exclusive of wine, may be obtained from Dr. R. L. Mackenzie Wallis, one of the honorary secretaries, at St. Bartholomew's Hospital, London, E.C.

The Services.

THE ARMY DENTAL CORPS.

BY Royal Warrant the formation of an Army Dental Corps has been authorised, which will be a joint service for the Army and the Royal Air Force. It will be administered by the Director-General of the Army Medical Service, and the personnel will be interchangeable between the two forces. Under regulations to be approved by the Army Council commissions, as lieutenants, will be granted to persons duly qualified, and officers will be eligible for promotion to the rank of captain on completion of three and a half years' service in the corps; while promotion to the rank of major and lieutenant-colonel to fill establishment will be made by selection of the Army Council. On the formation of the corps, certain appointments will be made in the rank of lieutenant-colonel and major to fill the establishment. The remainder of the appointments will be in the rank of lieutenant except in cases where service of three and a half years or more has been given as a temporary dental officer, when the rank of captain will be given. Service as a temporary dental officer will count towards the three and a half years for promotion to captain.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Lieut. G. L. Ritchie to be Surgeon Lieutenant Commander.

Surg.-Cmdr. J. A. L. Campbell is placed on retired list with rank of Surgeon Captain.

Surg.-Cmdrs. A. Woollcombe to the *Colossus*, and T. E. Blunt to Haslar Hospital.

ARMY MEDICAL SERVICE.

Col. E. M. Morphew is placed on half pay.

Col. C. K. Morgan retires on retired pay.

ROYAL ARMY MEDICAL CORPS.

Major J. Startin is placed on half-pay list on account of ill-health.

The undermentioned retire on retired pay: Col. J. McD. McCarthy, Lieut.-Col. A. F. Weston, and Major F. A. Stephens.

Capt. L. F. K. Way retires, receiving a gratuity.

Major F. T. Dowling relinquishes the acting rank of Lieutenant-Colonel.

Capt. D. T. M. Large to be temporary Major whilst specially employed.

Officers relinquishing their commissions:—Temp. Majors J. M. Mathieson and H. W. Wookey (retain the rank of Major). Temporary Captains retaining the rank of Captain: H. Bell, G. Cock, R. W. Harper, E. C. Lindsey, C. F. Maclachlan, O. Marshall, R. C. Phelps, H. Morell, and L. Fraser. Temporary Lieutenants retaining the rank of Lieutenant: E. P. O'Dowd and J. A. A. P. Scott.

GENERAL RESERVE OF OFFICERS.

A. L. Aymer, late Captain, R.A.M.C., to be Major.

SPECIAL RESERVE OF OFFICERS.

The undermentioned Captains relinquish their commissions and retain the rank of Captain: D. C. Pim, W. E. P. Briggs, E. R. W. Gilmore, S. P. Castell, K. McAlpine, J. L. Rowlands, and J. Aitkin.

TERRITORIAL FORCE.

Lieut.-Col. J. G. Martin to be Colonel and Assistant Director of Medical Services, West Lancashire Division.

Capt. A. A. Hingston to be Major.

Capt. R. F. Linton (late R.A.M.C.) to be Captain.

Capt. D. Buchanan is seconded.

Capt. L. R. G. de Glanville (late R.A.M.C.) to be Lieutenant.

INDIA AND THE INDIAN MEDICAL SERVICE.

Lieut.-Col. R. F. Baird, civil surgeon, Mussoorie, has been granted privilege leave for five months. Lieut.-Col. W. O. Anderson has been posted as Chief Medical Officer, N.W.F. Province. Major R. H. Lee holds charge of the appointment of Civil Surgeon, Ajmere, and Chief Medical Officer in Rajputana, temporarily in addition to his duties as Agency Surgeon in Kotah and Jhalawar. Lieut.-Col. L. J. M. Deas has been granted one year's combined leave. Major R. H. Lee officiates as Civil Surgeon, Ajmere. Lieut.-Col. F. A. Smith on return from leave has resumed charge of the duties of Residency Surgeon, Indore, and Administrative Medical Officer in Central India. Capt. T. L. Bomford has been appointed substantively pro tempore to be Resident Medical Officer, Medical College Hospital, Calcutta.

WAR HONOURS.

Appointments in the Most Excellent Order of the British Empire for services in connexion with the war have been made as follows:—Dr. M. A. J. de Lavis-Trafford, Senior Medical Officer, Red Cross Hospital, Turin, Italy, Officer of the Civil Division. Dr. W. L. Chubb, Medical Officer, Minley and Farnborough Court Auxiliary Hospitals, Hampshire, and Dr. E. Lloyd, in charge of relief and hospital work at Gaza, Members of the Civil Division.

MENTIONED IN DESPATCHES.

The following names are mentioned in a despatch, dated August 11th, from the General Commanding-in Chief, the British Army of the Black Sea:—Major-Gen. Sir M. P. C. Holt, K.C.B., K.C.M.G., D.S.O., K.H.S., A.M.S.; Lieut.-Col. and Bt. Col. W. H. S. Nickerson, V.C., C.B., C.M.G., R.A.M.C.; Capt. and Bt. Major (acting Lieut.-Col.) R. E. Barnsley, M.C., 84th Field Ambulance, R.A.M.C. Capt. W. Bird, 84th Field Ambulance, R.A.M.C.

Obituary.

CHARLES HIGGENS, F.R.C.S. ENG.,

CONSULTING OPHTHALMIC SURGEON TO GUY'S HOSPITAL.

Mr. Charles Higgens, who died suddenly while out shooting on Dec. 28th last, was born in 1846, and was educated at Brighton College and at Guy's Hospital Medical School, qualifying with the M.R.C.S. Eng., L.R.C.P. Lond., and L.S.A. in 1868. In 1871 he became F.R.C.S. Eng., and was appointed surgeon to the Central London Ophthalmic Hospital, and was assistant ophthalmic surgeon at Guy's Hospital two years later. In 1883 he became senior ophthalmic surgeon to Guy's and lecturer on ophthalmology in the medical school. Retiring in 1906 he was elected consulting surgeon. He was also for many years ophthalmic surgeon to the French Hospital and surgeon to the County of London War Hospital during the war.

Such is a brief record of Charles Higgens, who was a man of very lovable personality, and who enjoyed great and well-deserved popularity as well as the respect of a vast number of colleagues, senior and junior, and of pupils, all of whom admired his professional skill and resourcefulness and his high simple standards of conduct. The following is a picture of him by one who worked for many years in close association with him.

As a colleague Charles Higgens was markedly generous and always appreciative of work done for him by his juniors. He entrusted both his private and hospital work to them in any absence, and his experience was frankly shared with them. To his equals he was always cheery, wise, and full of common sense; and his honesty made him as ready to discuss any failures and disappointments in his cases as his successes, a trait that is not too frequently met with, while it is of far greater value for any man who is beginning an ophthalmic career to hear of the difficulties which may have to be avoided than to receive any long list of triumphs. His operating was good, he being of wiry physique, tireless, and entirely self-confident. He "impressed" his patients into confidence by his obvious capacity for the work he had to do—the assurance that he was equal to his job. *He invented no new operations, but he performed the "simple* extraction" of cataract in a perfect way, and his large practice was easily accounted for when one had an intimate knowledge of his straightforward way with his patients and his manual dexterity. As a consultant his younger colleagues *found him of great value; you could always take a difficulty* to Charles Higgens and be sure of sympathy and a concentration on it; he took the obvious and straightforward line, and was quite explicit in his decision. He did not always give elaborate reasons for his views—they were the result of long years of large and varied experience—but neither did he bother his head about possibilities and eventualities unlikely to occur.

He wrote little compared to some other ophthalmic surgeons holding positions as big; a small ophthalmic text-book of his had a large sale some years ago, but is now out of date and submerged by the never-ceasing stream of similar publications. More than anything else was he roused to write in censure of any "money-seeking merchants" in the profession, but only as a vent to his own feelings. Extreme honesty was his marked and finest trait, and such views were too outspoken for any but an editor thirsting for litigation, whom happily he never found. In his private life he was a sportsman at heart. Hunting and shooting were his relaxations on every opportunity, and advancing years never damped his ardour in these directions.

From such a description there emerges a very accurate picture of the man, and there may be added *to it some extracts from a sympathetic note received* from Mr. Tom Bird, consulting anæsthetist to Guy's Hospital, who lived with his friend for 14 years preceding Higgens's marriage. Mr. Bird says:—

"We resided together at 38, Brook-street in congenial companionship for 14 years. Our domestic partnership was broken in one sense by Higgens's marriage, but our personal and professional friendship remained inviolable until his passing away. I had reason to know the results of a great deal of his work, and positively I do not remember a single operation of his that went wrong in the half century over which my experience of that work extends—I am speaking, of course, of the operation per se. He was advanced in years when the war placed upon him hard work at the military hospital at Portland, but he delighted in the work, and *seemed sometimes to be inspired with a genuine desire to* tire out everybody else but himself. His manner of death was, I think, such as he would have wished."

Mr. Higgens left behind him very little written work beyond contributions to Guy's Hospital Reports, to the Transactions of the Royal Medical and Chirurgical Society, and of the Ophthalmological Society, and occasionally to the columns of THE LANCET. Among the last may be mentioned a note published in 1894 on 1925 Extractions of Cataract, and a paper published in 1907 on 130 Consecutive Extractions of Cataract without a Failure. In 1879 he published a little book on Ophthalmic Practice, and in 1903 the Manual of Ophthalmic Practice, referred to above, which was marked by the simplicity and straightforwardness of the accounts given of a number of diseases of the eye, and by the sensible and judicious advice in respect of treatment.

URBAN VITAL STATISTICS.

(Week ended Jan. 15th, 1921.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate population estimated at 18½ million persons, the annual rate of mortality, which had been 15·1, 16·6, and 14·0 in the three preceding weeks, declined to 12·8 per 1000. In London, with a population of 4½ million persons, the death-rate was 12·6, or 0·3 per 1000 below that recorded in the previous week, while among the remaining towns the rates ranged from 3·8 in Ilford, 4·8 in Ealing, and 4·9 in Acton, to 21·7 in Merthyr Tydfil, 23·9 in Sunderland, and 24·2 in Tynemouth. The principal epidemic diseases caused 224 deaths, which corresponded to an annual rate of 0·6 per 1000, and comprised 92 from infantile diarrhœa, 69 from diphtheria, 31 from whooping-cough, 20 from measles, 8 from scarlet fever, 3 from enteric fever, and 1 from small-pox. Whooping-cough caused a death-rate of 2·0 in Warrington, but the mortality from the remaining diseases showed no marked excess in any of the towns. The fatal case of small-pox belonged to Bristol. There were 4413 cases of scarlet fever, 2597 of diphtheria, and 1 of small-pox under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 4608, 2588, and 1 respectively at the end of the previous week. The causes of 26 of the 4556 deaths in the 96 towns were uncertified, *of which 7 were registered* in Birmingham, and 3 each in Manchester and Blackpool.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 16·2, 18·4, and *18·4 in the three preceding weeks, fell to 15·9 per 1000.* The 329 deaths in Glasgow corresponded to an annual rate of 15·6 per 1000, and included 11 from infantile diarrhœa, 5 from diphtheria, 4 from whooping-cough, and 1 each from small-pox, measles, and scarlet fever. The 133 deaths in Edinburgh were equal to a rate of 15·5 per 1000, and included 7 from influenza, 3 from measles, and 1 each from scarlet fever, diphtheria, and infantile diarrhœa.

Irish Towns.—The 145 deaths in Dublin corresponded to an annual rate of 17·9, or 0·8 per 1000 above that recorded in the previous week, and included 4 from infantile diarrhœa. The 146 deaths in Belfast were equal to a rate of 18·1 per 1000, and included 2 from whooping-cough.

VITAL STATISTICS OF LONDON DURING DECEMBER, 1920.

IN the accompanying table will be found summarised statistics relating to sickness and mortality in the City of London and in each of the metropolitan boroughs. With regard to the notified cases of infectious diseases, it appears that the number of persons reported to be suffering from one or other of the ten diseases notified in the table was equal to an annual rate of 12·3 per 1000 of the population, estimated at 4,358,309 persons; in the three preceding months the rates had been 11·3, 16·3, and 15·8 per 1000. Among the metropolitan boroughs the lowest rates from these diseases were recorded in *Paddington, Chelsea, the City* of Westminster, St. Marylebone, and Lambeth; and the highest in Hammersmith, Stoke Newington, Bethnal Green, Stepney, Poplar, and Deptford. One case of small-pox was notified during the month from the borough of Hampstead. The prevalence of scarlet fever was 26 per cent. less than in the preceding month; this disease was proportionally most prevalent in Hammersmith, Bethnal Green, Stepney, Poplar, Bermondsey, and Deptford. The Metropolitan Asylums Hospitals contained 4729 scarlet fever patients at the end of the month, against 3683, 5117, and 5508 at the end of the three preceding months; the weekly admissions averaged 590,

ANALYSIS OF SICKNESS AND MORTALITY STATISTICS IN LONDON DURING DECEMBER, 1920.

(Specially compiled for THE LANCET.)

* Including membranous croup.

against 603, 873, and 780 in the three preceding months. Diphtheria was slightly less prevalent than in the preceding month; the greatest proportional prevalence of this disease was recorded in Fulham, Islington, Stoke Newington, Holborn, Shoreditch, and Poplar. The number of diphtheria patients under treatment in the Metropolitan Asylums Hospitals, which had been 1773, 2284, and 2604 at the end of the three preceding months, numbered 2615 at the end of December; the weekly admissions averaged 316, against 266, 364, and 360 in the three preceding months. The prevalence of enteric fever was about equal to that in the four preceding months; of the 28 cases notified during the month, 4 belonged to Lambeth, 3 to Kensington, 3 to Camberwell, and 2 each to Fulham, St. Pancras, Poplar, and Southwark. There were 15 cases of enteric fever under treatment in the Metropolitan Asylums Hospitals at the end of the month, against 14, 19, and 16 at the end of the three preceding months; the weekly admissions averaged 2, against 3, 4, and 3 in the three preceding months. Erysipelas was proportionally most prevalent in Hammersmith, Fulham, the City of Westminster, Shoreditch, Bethnal Green, and Southwark. The 43 cases of puerperal fever included 5 in Lambeth, 4 each in Paddington, Hammersmith, Hackney, and Stepney, 3 in Bermondsey, and 3 in Woolwich. The 15 cases of cerebrospinal meningitis included 3 in Stepney, 3 in Poplar, and 2 in Wandsworth. No case of poliomyelitis was notified during the month.

The mortality statistics in the table relate to the deaths of civilians actually belonging to the several boroughs, the deaths occurring in institutions having been distributed among the boroughs in which the deceased persons had previously resided. During the five weeks ended Jan. 1st, 1921, the deaths of 6165 London residents were registered, equal to an annual rate of 14·8 per 1000; in the three preceding months the rates had been 9·9, 10·5, and 13·6 per 1000. The death-rates ranged from 11·0 in Hampstead, 11·6 in Greenwich, 12·1 in Woolwich, 12·3 in Wandsworth, 12·9 in St. Marylebone, 13·3 in Deptford, and 13·4 in Lewisham, to 16·2 in Islington, 16·3 in Bethnal Green, 16·4 in Holborn, 16·4 in Lambeth, 17·7 in Finsbury, 17·7 in Southwark, and 17·8 in Kensington. The 6165 deaths from all causes included 269 deaths which were referred to the principal infectious diseases; of these, 7 resulted from measles, 34 from scarlet fever, 118 from diphtheria, 19 from whooping-cough, 1 from enteric fever, and 90 from diarrhœa and enteritis among children under 2 years of age. No death from any of these diseases was recorded in the City of London. Among the metropolitan boroughs the lowest death-rates from these diseases were recorded in St. Marylebone, Hampstead, Bermondsey, Wandsworth, Deptford, and Greenwich; and the highest in Islington, Stoke Newington, Holborn, Finsbury, Shoreditch, and Poplar. The 7 deaths from measles were less than one-twelfth of the average number in the corresponding period of the five preceding years; of these, 2 belonged to Paddington. The 34 fatal cases of scarlet fever exceeded the average by 18; of these, 3 belonged to each of the boroughs of Stepney, Poplar, Lambeth, Camberwell, and Lewisham. The 118 deaths from diphtheria exceeded the average number by 33; the greatest proportional mortality from this disease occurred in Hammersmith, Islington, Stoke Newington, Holborn, Finsbury, and Poplar. The 19 fatal cases of whooping-cough were about one-third of the average; of these, 3 belonged to Kensington, 3 to Bethnal Green, and 3 to Battersea. One death from enteric fever was registered during the month, against an average of 6. The 90 fatal cases of infantile diarrhœa showed a decline of 10 from the average; the greatest proportional mortality from this disease occurred in Kensington, the City of Westminster, Islington, Shoreditch, Lambeth, and Camberwell. In conclusion, it may be stated that the aggregate mortality in London during December from these principal infectious diseases was 23 per cent. below the average in the corresponding period of the five preceding years.

ROYAL SANITARY INSTITUTE.—A sessional meeting will be held on Jan. 28th in the Guildhall, Exeter, at 4.30 P.M., jointly with the West of England branch of the Society of Medical Officers of Health, when a discussion on the Sanatorium Question will be opened by Dr. E. Ward. The chair will be taken by Professor H. R. Kenwood. On Jan. 29th at 9.30 A.M. a short discussion on Housing will be opened by Dr. P. H. Stirk and will be followed by a visit to new houses and insanitary areas. Those proposing to attend are asked to notify the honorary local secretary, Dr. P. H. Stirk, Southernhay W., Exeter, not later than Jan. 22nd.

Correspondence.

"Audi alteram partem."

TABES: ITS EARLY RECOGNITION.

To the Editor of THE LANCET.

SIR,—Dr. John Donald accuses me of pessimism in regard to the treatment of syphilis on the ground that I would advise every patient who contracts that disease to be treated at intervals for the rest of his life. He states that this must not pass unchallenged, but fails to lay down anything in the way of a challenge. The best he can do is to state that he discharged the cases of syphilis which he treated in the army "with much assurance," and this is exactly what the medical profession has been doing without any justification for many years. The position is much the same as in the old days of mercury. If you take a hundred cases of syphilis and treat them all according to the standard methods of the day you are justified in believing that a certain proportion will have been cured, but you cannot honestly tell any single one of these patients that his disease has been eradicated. This is not pessimism, it is the truth. Personally I am optimistic enough to believe that if this truthful line were adopted and the patients urged to have periodic courses of treatment for the rest of their lives we should see very much less of the late syphilitic diseases than we do. As it is, a large amount of our time is taken up with the treatment of syphilitic affections of patients who have been told years ago that they have been cured of their disease, and this must go on so long as we lack the means of determining whether a cure of the disease has been effected.

I am, Sir, yours faithfully,

E. FARQUHAR BUZZARD.

Wimpole-street, W., Jan. 17th, 1921.

To the Editor of THE LANCET.

SIR,—The comments made by Dr. John Donald in THE LANCET of Jan. 15th upon Dr. E. Farquhar Buzzard's article on Jan. 8th, under this title, and with reference to the duration of the treatment of syphilis, are somewhat extraordinary. In his article Dr. Buzzard expresses the opinion—the correctness of which is daily becoming more recognised by syphilologists—that it is impossible to say in any given instance that a patient is cured of syphilis. The most that can be done is to tell the patient that he is non-infectious. To get a patient to this stage is comparatively easy. But, having reached this stage, and having obtained a negative blood-Wassermann, it is certainly not justifiable to stop all treatment and give the assurance that aortitis, aneurysm, or central nervous system syphilis are now impossible. The tyranny of the Wassermann reaction is at its worst when, after a short course of treatment and a negative blood test, the negative finding is accepted as a criterion of cure. It is by no means uncommon, even after prolonged treatment of primary syphilis, to find the blood negative and the cerebro-spinal fluid positive. It is unfortunate that when early syphilis is treated by the general practitioner, the cerebro-spinal fluid is so seldom subjected to serological and cytological examination. The treatment of syphilis is something more than trying to obtain negative blood-Wassermann results. In many cases which are non-infectious a permanent negative is impossible. It is not rare to find the blood negative and the patient suffering from undoubted cutaneous syphilis. The position is that we cannot guarantee to cure syphilis. As a test of cure the Wassermann reaction is treacherous—perhaps worthless. The only real test is an undoubted re-infection, but many of the reported cases are merely recurrences.

Dr. Buzzard's conclusions are perfectly correct. The tabetic must remain under treatment for the remainder of his life. It will be safer for the man with the primary chancre if he does likewise. Once having had syphilis, the only thing which precludes the reappearance of some syphilitic manifestation after the stoppage of treatment is death. Re-infection, the only test of cure, is rare. The long sorrowful tale of vascular degenerations and the experience of the neurologists show that, even after what is generally considered adequate treatment and cure, we have been living in a fool's paradise. There has been too much foolish optimism in burying our heads, ostrich-like, under sheaves of negative blood-Wassermann reports and imagining ourselves secure.

Dr. Donald rightly insists upon early diagnosis. The most severe attack upon syphilis can only be made in the chancre stage; but that attack, if it is to be of any avail, must be an overwhelming one. When Dr. Donald ventures "the dogmatic assertion that if a patient first comes under treatment while the blood is still negative (it is here the Wassermann test is of prime value) and receives the usual course of 2·6 g. of "606" and 8 gr. of mercury, the disease will be 'knocked out,'" he is merely scattering a few more negative Wassermann reports upon the head of the ostrich. His parenthetical remark is somewhat incomprehensible, and the "knocking out" of syphilis with 2·6 g. of "606" and 8 gr. of mercury is like trying to cure the Pope of the gout by putting a mustard plaster on the dome of St. Peter's.

Nervous syphilis has, within the last decade, become 20 times more frequent than it was in the preceding one. The main causes for this are undoubtedly inadequate treatment and the fetish of the negative blood-Wassermann as the criterion of cure. Salvarsan, properly used and its limitations appreciated, is a most valuable drug. It rapidly puts the patient in a non-infectious state, and it causes the disappearance of symptoms. But neither salvarsan nor mercury, either combined or separately, cures syphilis except in very rare cases. The curse of salvarsan is that both the patient and his medical attendant are too prone to regard the rapid disappearance of symptoms as equivalent to cure, and the result is that only the totally inadequate short course as advocated by Dr. Donald is administered.

My experience in dealing with syphilis in the army, at a venereal clinic and in private, is that it is just the cases which have been treated along these lines who are now appearing with symptoms of central nervous system syphilis. The course of treatment I now adopt in primary syphilis is based upon an appreciation of these facts, and has for its object the protection of this master tissue of the body. It is as follows:—Neokharsivan is given intravenously once weekly for six weeks, then 10 minims of mercurial cream are injected intramuscularly for four weeks. Then follow four weekly injections of neokharsivan and another four weeks of intramuscular mercury. Neokharsivan is again given for the succeeding three weeks, and then intramuscular mercury for four weeks. This is succeeded by two weekly doses of neokharsivan and the mercury is repeated for another month. A week after the last mercury injection one dose of neokharsivan is administered. The whole course lasts 32 weeks. The patient returns in four months, when the nervous system and the cerebro-spinal fluid are examined. The symptoms having disappeared, salvarsan is now replaced by mercury alone, of which two courses are given a year for the next two years. The patient is then recommended, as an "insurance policy," to have an annual mercurial course for the rest of his life.

Sufficient time has not yet elapsed to publish the after-histories of these cases. A course of treatment similar to the foregoing has been in operation for over a year at the Illinois Social Hygienic Dispensary, Chicago, and in this country, at the Venereal Clinic at Wigan. It is found that both at clinics and in private practice patients are very amenable to this treatment and attend regularly when they have been properly impressed. If several clinics were to carry out this scheme it would be interesting to compare results in ten years' time.

I am, Sir, yours faithfully,

Manchester, Jan. 15th, 1921. E. T. BURKE.

THE FUTURE OF THE POOR-LAW INFIRMARIES.

To the Editor of The Lancet.

Sir,—Dr. C. M. Wilson's letter in your issue of Jan. 15th may soothe hurt feelings, but he must forgive those who read his address and took it that he intended the plain meaning of his words. The medical superintendents are, to a peculiar degree, responsible for the infirmaries. Some of us have spent many years confronting their problems. Dr. Wilson proclaims our defects and does not hesitate to instruct us as to how we should proceed. But in one direction, at least, he does not, in my opinion, point out the right path of progress. He appears to indicate that a medical staff of the quality and dimensions of that of a general teaching hospital is the goal towards which the infirmaries should strive. If we are wise we shall attempt no such thing. Whatever changes occur the infirmaries will remain a charge upon public funds. They must be conducted economically. Every member of the medical staffs will quite justly demand to be properly remunerated. It is clear also that the main, almost the sole, function of the infirmaries will continue to be the treatment of the sick. They will never take any but a quite secondary place in medical education. Under such circumstances a staff of 20 residents and 30 consultants for, say, 500 beds would be immensely costly, quite unnecessary, and indeed preposterous.

At the present time the basis of the medical staffs of the infirmaries is the general practitioner, for what in the world else is the resident medical officer? This must remain. The medical work must be carried out mainly by general practitioners, whether whole or part time is debatable, but still general practitioners. And the specialist must play precisely the same rôle in the infirmaries as he plays in general practice. This principle is, in my opinion, fundamental.

Along these lines the medical superintendents have striven and are striving to progress. Their object is to obtain for the infirmaries an adequate—that is to say, what they consider an adequate—staff of efficient general practitioners or medical officers as they are usually called, and to make such provision as will ensure that they can obtain the services of specialists when they require them. They do not wish, or, at any rate they should not wish, to staff the infirmaries with specialists as the hospitals are staffed, and reduce the medical officers to the position of dressers or clerks.

With regard to the question of linking up with the general hospitals, I believe this to be cordially desired by the majority of medical superintendents. Dr. Wilson agrees that the spirit in which we approach one another is all-important. It is because they inevitably arouse resentment and antagonism that I beg that, in future, we may be spared the prominent publication of such essays by amateurs as were delivered at the Harveian Society.

I am, Sir, yours faithfully,
H. W. Bruce,
Medical Superintendent, Southwark Infirmary, and
Secretary to the Society of Infirmary
Medical Superintendents.
Jan. 15th, 1921.

PNEUMONIA AND MEMBRANOUS COLITIS.

To the Editor of The Lancet.

Sir,—Everyone will agree with Dr. E. Cronin Lowe (The Lancet, Jan. 15th, p. 112) as to the rarity of membranous colitis with pneumonia, but it is of interest that Bristowe in 1884, in his "Theory and Practice of Medicine," fifth edition, p. 407, writing of the morbid appearances met with in pneumonia, mentions "intestinal congestion, with sometimes membranous patches on the mucous surface of the large intestine." The occurrence of acute colitis with pneumonia is described in the article on Diseases of the Colon in Allbutt and Rolleston's "System of Medicine (1907, Vol. III., p. 815), and it is stated to be extremely rare. There is nothing to show whether in these cases the pneumonia was, as in Dr. Lowe's cases, influenzal, but as his cases are described as septicæmic, it is to be remembered that several cases of severe septic acute colitis, sometimes membranous, are mentioned on p. 814 and p. 824 of this article. In these cases the formation of a membrane is only an expression of the intensity of the inflammatory process. Very occasionally pneumonic infection may show itself in the bowel. I remember a man who was taken ill suddenly with a rigor and high temperature; he had also bloody diarrhœa, but no abnormal signs in his lungs. The diagnosis of pneumococcal infection was made and turned out to be correct, for next day the patient had characteristic pulmonary signs.

I am, Sir, yours faithfully,
London, Jan. 15th, 1921. W. Hale-White.

THE CULTURAL DIAGNOSIS OF ENTERIC FEVER.

To the Editor of The Lancet.

Sir,—The article which Dr. J. C. G. Ledingham contributed to your issue of Jan. 8th, and the letter from Dr. R. P. Garrow which appears to-day, indicate the serious disagreement still existing among those who are interested in the diagnosis of enteric infections among inoculated individuals, whether from the clinical or the bacteriological side, with regard to the interpretation of repeated agglutination tests. As the question is one of considerable importance, and as further discussion seems inevitable, and indeed desirable, may I suggest that the first requisite for a profitable consideration of the matter is a clear definition of the points at issue? It is unlikely that any argument which lays stress on an opposition between the clinical and bacteriological points of view, or which attributes to an opponent "the desire" to prove a given hypothesis will lead to any satisfactory result. Most of those, clinicians or bacteriologists, who are concerned in the solution of such a question are interested only in arriving at the truth. The regrettable habit of drawing an unhelpful distinction between the acquirement of new knowledge and its application to practical medicine, to which you have yourself drawn attention, and which is usually marked by the use of the word "academic," merely indicates a lack of understanding of scientific method.

The question raised by Dr. Ledingham is, however, of the first importance, and it was considered at some length in the report[1] from which you have already allowed me to quote. I do not suppose that there is a single bacteriologist who would not prefer to base a diagnosis of enteric infection on a positive blood-culture rather than on the results of agglutination tests. The position is simply this. It has been found by numerous workers that a proportion of cases of undiagnosed pyrexia, which have yielded consistently negative results on repeated cultural examination, show an agglutination curve having all the characteristics which have been accepted by certain authorities as diagnostic of an active infection with the organism concerned. In some of these cases the cultural tests have of necessity been carried out under conditions so disadvantageous as to minimise the significance of the negative results obtained; in others they have been made under circumstances entirely favourable to successful isolation of the infecting organism. The problem remains the same. What meaning are we to attach to a "typical" agglutination curve in the absence of confirmatory evidence? The answer to this question would seem to depend mainly on whether or no similar fluctuations can be shown to occur in cases in which enteric infection can be excluded. If so, then we must clearly discard all evidence as to the incidence of this disease among our armies in the late war, which depends upon this method of investigation.

The conclusion to which our own work led us, and which still expresses my own opinion, will be found in our report:—

"We must own to a considerable reluctance to rely on diagnoses made on serological tests alone. ...... Having regard to all the facts, including the clinical features of the cases, it seems to us that the weight of evidence is clearly in favour of the probable correctness of the serological diagnoses. ...... This investigation yields a tentative answer (to the question of the probable proportion of enteric infections among cases of undiagnosed pyrexia among our armies in France) which will be confirmed or refuted by the accumulation of evidence obtained by other workers."

---

THE INSURANCE MEDICAL RECORDS.

To the Editor of THE LANCET.

SIR,—Your leading article in THE LANCET for Jan. 8th will cause considerable distress, a great deal of irritation and ill-feeling among medical men, and particularly in the section unfortunately situated as "panel practitioners." The records are of the most foolish type for statistics; they were never submitted for the approval or otherwise of those who have to keep them, and many, if not most, will consider they are being put to do, at a great expense of time, very useless work. But the chief feeling caused by your article will be that you should lend your journal for propaganda work which is far from the interests of, I hope, a great proportion of your readers and to lend your pages for an article apparently written by one who will never be called upon to keep these records or to sign insurance patients' certificates. Personally I always thought THE LANCET was a "cut" above the tone adopted, which savours of Government contamination.

I am sure that if you, Sir, will put the question in your next issue, and allow it to be answered by postcard, there will be very few panel practitioners found in favour of the present type of records, which, I believe, are to cost the country in taxes another £30,000 a year.—I am, Sir, yours faithfully,

Kencott, Glos., Jan. 17th, 1921. F. W. PILKINGTON.

⁂ The form of the records is imposed by the need to limit the clerical labours, inasmuch as the records on ethical grounds must be kept by practitioners. We agree that in fuller shape such information would have far greater scientific value. Our correspondent has not read very carefully the article which he condemns, or he would have seen how far we are at one with him.—ED. L.

POST-OPERATIVE MORTALITY OF APPENDICITIS.

To the Editor of THE LANCET.

SIR,—Dr. Herbert H. Brown, writing in association with Mr. H. M. Cade on this subject in THE LANCET for Jan. 15th, provides food for serious thought. He states that during the first 48 hours after the commencement of a case and also during the second week, when an abscess may have formed, operation is practically safe, but during the intervening period there is great danger, even to the extent of 22·7 per cent. of a fatal issue. Those among us who can look back for 30 or 40 years to a time when the terms typhlitis and perityphlitis were in common use will remember cases of complete recovery after large swellings in the region of the right iliac fossa, and which under watchful and expectant treatment wholly disappeared, leaving no ill-results. My practice has always been to watch cases carefully, and not to advise operation until I have considered it necessary, and as over a period of 40 years I can recall no fatal case in my practice I am inclined to think there are people living who if they had been hurried off for operation would have helped to swell the high death-rate. It is quite certain that in general practice the great majority of cases will not come under the surgeon's hands within the first 48 hours, and in face of the statistics given in Dr. Brown's article it surely is both logically and morally wrong to put any patient to so great a risk during the dangerous period, except in very urgent cases.

I am, Sirs, yours faithfully,
F. L. NICHOLLS, O.B.E.

Fulbourn, near Cambridge, Jan. 19th, 1921.

MEDICAL PRACTICE BY FOREIGNERS IN SPAIN.

To the Editor of THE LANCET.

SIR,—In your issue of Jan. 1st (p. 58) you give the conditions as laid down by an old law which has just been rescinded by a Royal decree of Dec. 27th, 1920, owing to agitation by the Spanish medical profession. Foreigners will now only be admitted to practice in Spain if their respective countries give equal facilities to Spanish medical men, otherwise they must go through the whole course of study. The Royal decree translated reads as follows:—

Art. (1) The Article 96 of the law of public instruction of the year 1857 is re-established in all its vigour and effect, so far as it refers to temporal registration of diplomas obtained in foreign countries authorising practice in Spain.

(2) The Ministers of Public Instruction and Fomento (agriculture, engineering, &c.) in future can only authorise the registration of diplomas of the following professions: medical, dental, engineering, and foremen of mines, to such, in whose own country, diplomas conferred in Spain for the said professions will be recognised for registration and permission to practise.

(3) As soon as the time expires of authorised foreign diplomas of above professions such authorisation lapses.

(4) Any existing decree opposing the present to be null and void.

This decision is of importance to the medical profession in your country.

I am, Sir, yours faithfully,
C. W. HUYSSEN,
Surgeon to Rio-Tinto Cos. Hospital in Huelva.

Huelva, Jan. 8th, 1921.

Medical News.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—A quarterly meeting of the Council was held on Jan. 13th, Sir Anthony Bowlby being in the chair.—The President reported that the Prince of Wales would be present at the Hunterian festival dinner on Feb. 14th to receive the Diploma of Honorary Fellowship, to which His Royal Highness was elected on July 24th, 1919.—A vote of congratulation was passed to Sir Charles Ryall on having received the honour of knighthood.—Mr. C. H. Fagge was introduced and admitted a member of the Court of Examiners.—Reports were read from the secretary of the Conjoint Examining Board respecting candidates found qualified for the Diploma of Public Health of the two Colleges, for the Diploma in Tropical Medicine and Hygiene, and for the Diploma in Psychological Medicine. A list of the successful candidates is given below.—A letter was read from Mr. Philip Franklin stating that the Onodi Collection of Nasal Anatomy had been purchased by the Onodi Committee with the object of presenting it to the Royal College of Surgeons of England. It was agreed, on the recommendation of the Museum Committee, that Mr. Philip Franklin be informed that the Council is willing to accept the Onodi collection and to undertake the responsibility of preparing and mounting the specimens for exhibition in the Museum, and that he be requested to convey to the donors the thanks of the Council. The Conservator expressed the opinion that it would take the greater part of two years for the Museum Prosector to prepare the specimens for exhibition, and that the cost of their preparation would amount to about £650.—A report was received from the Finance Committee recommending a rearrangement of fees payable for admission to the several examinations for the Licence in Dental Surgery. This was adopted and was rendered necessary by a revision of the Regulations made by the Council on the recommendation of the Board of Examiners in Dental Surgery. Under these revised Regulations the examinations in General and Dental Anatomy and Physiology are separated from the examinations in General and Dental Surgery and Pathology, and now form Part III. of the First Professional Examination for the Licence, and candidates may enter for examination in these subjects after completing six months' study during the ordinary sessions at a recognised medical and dental school.—Mr. W. G. Spencer was reappointed member of the Central Council for District Nursing in London for three years from Jan. 1st, 1921.—Sir William Thorburn was appointed a member of the Court of the University of Liverpool for three years from Jan. 1st, 1921.—On a motion of Sir George Makins a committee was appointed to consider the question of establishing additional examinations in Ophthalmology and in Oto-Rhino-Laryngology for candidates who desire to take them after having passed the examination for the Fellowship.

Diplomas in Psychological Medicine, in Tropical Medicine and Hygiene, and in Public Health were conferred (conjointly with the Royal College of Physicians) upon the following candidates:—

Diploma in Psychological Medicine.—M. Dia, Cairo and St. Mary's; E. D. T. Hayes, Trin. Coll., Dublin; O. Sidney Martin, Univ. Coll.; and H. W. Parnis, Malta.

Diploma in Tropical Medicine and Hygiene.—G. V. Allen, Belfast and London Sch. of Trop. Med.; J. Anderson, Glasgow and London Sch. of Trop. Med.; S. C. Basu, Calcutta and London Sch. of Trop. Med.; C. J. Caddick and W. B. A. K. Cullen, Edinburgh and London Sch. of Trop. Med.; A. Dasgupta, Calcutta and London Sch. of Trop. Med.; A. A. Denham, Edinburgh and London Sch. of Trop. Med.; A. M. El Kirdany, St. Bart.'s and London Sch. of Trop. Med.; R. E. Flowerdew, Aberdeen and London Sch. of Trop. Med.; C. H. Heppenstall, Leeds and London Sch. of Trop. Med.; L. C. D. Hermitte, Edinburgh and London Sch. of Trop. Med.; F. V. Jacques, Bristol and London Sch. of Trop. Med.; Z. Khaled, Cairo and London Sch. of Trop. Med.; P. T. Liang, St. Thomas's and London Sch. of Trop. Med.; R. H. Liscombe, Univ. Coll. and London Sch. of Trop. Med.; A. R. Mehta, Lahore and London Sch. of Trop. Med.; A. S. Paranjpe, Edinburgh and London Sch. of Trop. Med.; H. B. Parker, London Sch. of Trop. Med.; A. H. Patel, Bombay and London Sch. of Trop. Med.; Evelyn Bessie Salter, Bristol and London Sch. of Trop. Med.; R. Silcock, St. Mary's and London Sch. of Trop. Med.; S. Somasundram, Ceylon and London Sch. of Trop. Med.; W. R. Taylor and A. S. Westmorland, St. Mary's and London Sch. of Trop. Med.; and H. G. Wiltshire, Cambridge and London Sch. of Trop. Med.

Diploma in Public Health.—P. F. Alderson, Middlesex and Haslar; Madeline S. Baker, Dublin; T. B. Batchelor, Oxford, London, and King's Coll.; W. W. Boyce, Dublin; J. W. Caton, Durham and Univ. Coll.; H. W. Catto, Guy's; K. Comyn, Cambridge and King's Coll.; T. A. Fuller, Edinburgh and Univ. Coll.; K. A. Gandhi, Bombay and Univ. Coll.; D. H. Goffen, Univ. Coll.; E. St. G. S. Goodwin, Cambridge and St. Thomas's; D. N. Gore, Bombay and Univ. Coll.; A. J. B. Griffin, Liverpool and Univ. Coll.; P. H. Henderson, Edinburgh and Royal Army Med. Coll.; Eileen Mabel Hewitt, Dublin and King's Coll.; E. T. Holden, Birmingham and Cardiff; P. G. Horsburgh, St. Bart.'s and Univ. Coll.; T. S. Keith, Guy's; N. S. Kotwall, Bombay and Roy. Inst. Pub. Health; T. A. Lawder, Dublin and Univ. Coll.; J. T. Macnab, London and Univ. Coll.; A. N. R. McNeill, Glasgow; C. T. Maitland, St. Bart.'s; Mary Martin, Edinburgh and London; J. S. Ranson, King's Coll.; H. J. Simson, Edinburgh and Univ. Coll.; O. C. S. Tandy, Dublin and King's Coll.; A. Viney, St. Thomas's and Univ. Coll.; A. S. Wakely, King's Coll.; and A. Woollcombe, St. Bart.'s and Univ. Coll.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—At the Second Professional Examination in anatomy and physiology, held from Jan. 3rd to 9th, for which 129 candidates presented themselves, 70 were approved and 59 were rejected. The following are the names and medical schools of the successful candidates:—

W. E. Airey, Manchester; H. S. Allen, Cambridge and St. Thomas's; R. H. Amin, Guy's; W. B. Arnold, St. Bart.'s; E. E. E. Attale, St. Thomas's; G. F. Axon, King's Coll.; N. F. Azer, Cairo and King's Coll.; M. Bannounah, Guy's; R. C. Baxter, Charing Cross; D. R. Blunn, London; A. J. Boase, St. Thomas's; W. R. B. Booth and J. Chronnell, Manchester; W. Clark, King's Coll.; D. B. D'Alwis, Ceylon and London; J. R. Davies, St. Thomas's; H. C. de Penning, St. Mary's; G. A. Dolman, Cambridge; G. P. Driver, St. Bart.'s; Helen Mary Du Buisson, King's Coll; R. G. Eastwood, Leeds; Winifred Phœbe Edmunds, King's Coll.; L. C. J. Edwards, London; M. Farid, Birmingham; J. L. Faull, Guy's, Dorothy E. Galbraith, London Sch. of Med. for Women; J. E. Gardner, Edinburgh; F. W. Gayford, Middlesex; G. H. C. Harding, Liverpool, M. Hawke, Guy's; D. W. Hoodless, King's Coll.; L. G. Housden, Guy's; Katherine Edith Winifred Hulse, King's Coll.; Theresa Hettie Humphries, London Sch. of Med. for Women; N. I. H. Ibrahim, Sheffield; C. M. Jennings, W. M. Jones, and C. de W. Kiteat, St. Bart.'s; A. H. Kretchmar, Edinburgh; J. L. Lewthwaite, Liverpool; P. M. Lissack and J. Massie, St. Thomas's; Gertrude Mary Mayhall, Leeds; V. S. Monie, Edinburgh; O. G. Morris, Guy's; L. N. Moss, Cambridge; E. E. Neser, Guy's; A. P. Pearce, Leeds; V. D. Pennefather, L. S. Perera, and A. J. Reed, London; G. F. Rowbotham, Manchester; Mary Kathleen Ruddy and H. Rundstrom, King's Coll.; A. Schofield, Cambridge and St. Mary's; T. Seshachalam, Madras and London; K. S. M. Smith and N. Smith, St. Bart.'s; Edith Clara Summerskill, King's Coll.; H. H. D. Sutherland, St. Bart.'s; R. G. Tame, Guy's, T. B. Thomas, St. Bart.'s; A. Tom, Guy's; Henrietta Trend, London Sch. of Med. for Women; G. C. Vaughan, Birmingham; J. N. Wheatley, London; May Whittaker, King's Coll.; H. C. M. Williams, St. Bart.'s; and F. Woolford and T. Wooldridge, Guy's.

Materia Medica and Pharmacology.—Janet Mary Breakwell, Cambridge and Birmingham; G. Cohen, Guy's; A. C. D'Souza, Manchester; M. P. de Villiers and Margaret Findlay, London Sch. of Med. for Women; J. Fredman, St. Thomas's; G. Giloi, Middlesex; A. Gordon, M. Honigsberger, and C. E. Keast, Guy's; Doris Ethel Keeves, Birmingham; K. L. E. Kellgren, London Sch. of Med. for Women; M. A. Lautre, St. Thomas's; P. J. Levy, Guy's; Edna Lock, King's Coll.; J. Lurie, St. Thomas's; F. Martin, Guy's; E. B. Moffat, London Sch. of Med. for Women; A. L. te W. Naude, St. Thomas's; E. E. Neser, Guy's; R. F. A. Philpott, Oxford, Edinburgh, and St. Thomas's; F. R. Ratnagar, Guy's; J. Seelenfreund, London; Mary Agnes Elizabeth Somers, Bristol; Y. A. Sunbul, St. Mary's; Lucy Maud Summerhayes, St. George's; H. G. Triay, Edinburgh and St. Thomas's; F. S. Vaughan, Birmingham; M. Weinbren and R. E. Williams, Guy's.

UNIVERSITY OF OXFORD.—*Radcliffe Travelling Fellowship, 1921.*—An examination for a Fellowship, of the annual value of £200, tenable for three years, will be held during the present term, commencing on Tuesday, Feb. 22nd, at 10 A.M. Candidates must have passed the Final B.M. Examination not more than four years ago. The successful candidate must before election declare that he intends to devote himself during the period of his tenure of the Fellowship to the study of medical science and to travel abroad with a view to that study. The examination will occupy four days. Papers will be set in physiology, pathology, and preventive medicine, and a subject will be proposed for an essay; there will also be a practical examination in pathology. Any candidate desiring to offer in addition a special branch of either medicine or surgery must send notice of this to the Regius Professor of Medicine on or before Feb. 2nd. All intending candidates should send their names, addresses, qualifications, &c., to the Regius Professor of Medicine, University Museum, Oxford, on or before Feb. 2nd.

Ethnology of the Nile Valley.—A special course of lectures on the Ethnology of the Nile Valley will be delivered at Barnet House on Mondays at 5 P.M. during the present term by Dr. C. G. Seligman, F.R.S.

Degree days.—The degree days appointed for the present term are: Jan. 20th, at 10 A.M.; Feb. 12th, at 2.30 P.M.; March 3rd, at 10 A.M.; March 19th, at 10 A.M.

UNIVERSITY OF LONDON: *Middlesex Hospital Medical School.*—The following Emeritus lectures, to which visitors are invited, will be held this session at 3 P.M.: On Feb. 1st, 3rd, and 8th Surgeon-Rear-Admiral P. W. Bassett-Smith will lecture on Mediterranean Fever, Malaria, Trypanosomiasis respectively; on Feb. 22nd Sir Alfred Pearce Gould will lecture on Surgery; and on Feb. 25th Sir Richard Douglas Powell will lecture on the Ætiology of Phthisis. Subsequent lectures will be announced in our Medical Diary.

Dr. G. H. R. Gibson has been appointed a Deputy Commissioner of the General Board of Control for Scotland.

ROYAL MEDICAL BENEVOLENT FUND.—At the last meeting of the Committee held on Jan. 11th 24 cases were considered and £255 voted to 18. The following is a summary of some of the cases relieved.

Daughter, aged 68, of M.R.C.S.Eng. who practised at Brighton and died in 1874. Applicant has supported herself for some years by teaching drawing and painting, but owing to age and deafness now unable to obtain pupils. Only certain income £26 per annum and a gift from friends of £10. Rent £20 per annum. Voted £18 in 12 instalments.—Daughter, aged 44, of M.R.C.S.Eng. who practised in the Navy and in Cornwall and died in 1918. Owing to ill-health applicant is unable to earn her own living and is entirely dependent on her mother, whose income is very limited. Until recently applicant's mother was an annuitant of the Fund, but gave this up to enable her to take the old-age pension. Voted £10 in two instalments.—L.S.A.Lond., aged 74, married, practised at Ledbury. Applicant had to give up practice as sight was failing, and through serious illness and several operations had to give up work entirely. Twelve months ago he underwent an operation for cataract, which was a failure; he is now awaiting another operation on the other eye. Has been staying with a relation, paying 10s. per week out of savings, but these are now exhausted, and only income 10s. per week from old-age pension, which pays for applicant's board, &c. Voted £26 in 12 instalments.—Wife, aged 39, of M.D.Dub. Husband missing. Was in practice in South Africa. Applicant has not received any support from her husband since July, 1920, for herself and son, aged 3 years, and she has been living on her savings; these are now reduced to 30 Rent 6s. per week. Applicant is anxious to take a post as a lad help and to find a home for her little son. Voted £10 in tw instalments.—Widow, aged 53, of M.R.C.S. Eng. who practised i London and Lincolnshire. Applicant earns her own living b giving music and singing lessons. Her daughter, aged 26, help her aunt with whom she lives, but owing to a breakdown th doctor orders her away for a rest and applicant asks for help t defray the expense. Applicant's rent, 5s. per week, with use sitting-room and piano with which to give her lessons in return f lessons in singing and music to nieces of landlady. Relieved s times £48. Last time £10 in two instalments, December, 1918. Vote £15 in two instalments.—Widow, aged 40, of M.R.C.S. Eng. wh practised in Swansea and Liverpool. Applicant, an invali and her daughter, aged 12, dependent upon aged mother. A allowance of £20, made by various people towards daughter schooling. Relieved six times, £72. Last time £12 in 12 insta ments, January, 1920. Voted £18 in 12 instalments.—Daughte aged 48, of F.R.C.S. Irel. who practised in India and di in 1899. Applicant shares house with a friend, and they deri and share a small income from letting rooms. Applicant's to income during last 12 months £40. Relieved once £10, Janua 1920. Voted £10.—Daughter, aged 44, of F.R.C.S. Irel. w practised in India and died in 1899. Applicant shares a cotta with a friend, and they make a small income by taking boarde Total income for 1920 £75. Owing to high cost of living and upke of cottage applicant requires help. Relieved once £10, Janua 1920. Voted £10.

Subscriptions may be sent to the honorary treasurer, Charters J. Symonds, C.B., F.R.C.S., at 11, Chandos-stre Cavendish-square, London, W. 1.

London Hospital: Liddle Triennial Prize.—This prize, value £120, in the gift of the London Hospital, has been awarded for the year 1920 to Surgeon-Commander S. F. Dudley, O.B.E., M.D., R.N., and Professor James McIntosh, M.D.

Complimentary Dinner to Sir Robert Jones.—A dinner to Major-General Sir Robert Jones will be held on Monday, Jan. 31st, at 7 P.M., at the Midland Adelphi Hotel, Liverpool, on the occasion of the presentation of his portrait by his old colleagues and friends at the Royal Southern Hospital, Liverpool. The Earl of Derby will preside. Tickets, price £1 1*s.* each, may be obtained from Mr. T. R. W. Armour, F.R.C.S. Edin., 42, *Rodney-street, Liverpool.*

The Welfare of Miners.—The Committee just appointed to manage the fund constituted under Section 20 of the *Mining Industry Act, 1920, for the improvement of the* social well-being, recreation, and conditions of living of workers in or about coal-mines, includes the names of Lord Gorell, as chairman, and Professor E. L. Collis. Communications intended for the Committee should be addressed to Mr. W. G. Nott-Bower, Acting Secretary, at the Mines Department, 46, Victoria-street, London, S.W. 1.

National Hospital for the Paralysed and Epileptic.—A two months' post-graduate course in Neurology will begin on Jan. 24th, when Dr. Greenfield will give the first of three lectures on Cerebro-spinal Fluid, at 3.30 P.M. Lectures and demonstrations will subsequently be given by Dr. J. S. Collier, Dr. Grainger Stewart, Dr. Risien Russell, Dr. Farquhar Buzzard, Dr. J. Taylor, Dr. Gordon Holmes, Dr. H. H. Tooth, Dr. S. A. K. Wilson, Mr. P. W. G. Sargent, Mr. S. Scott, Mr. D. J. Armour, Dr. Russell J. Reynolds, Dr. Saunders, and Dr. Hinds Howell, and will be announced in the medical diary of THE LANCET. The fee for post-graduate course (£7 7*s.*) should be paid to the Secretary of the Hospital at the office. A special arrangement can be made for students who can attend one day a week only. Holders of the Fellowship of Medicine's ticket will be admitted free. Those wishing to undertake Practical Pathology, for which a special fee is charged, should apply to Dr. Greenfield.

Scurvy in Pigs and Poultry.—*On Jan. 14th* Dr. R. H. A. Plimmer, chief bio-chemist of the Rowett Animal Nutrition Research Institute at Craibstone, Aberdeen, lectured before a joint meeting of the Aberdeen University Scientific Association and of the Agricultural Society at Marischal College on "The Need of Vitamines by Man and Animals." Dr. Plimmer referred to the work of Hopkins, Osborne, Mendel, McCollum and Davis, Funk, and Lind, and traced the history of the discovery of the accessory food substances and of the treatment, preventive and curative, of deficiency diseases. He emphasised the fact that the over-cooking of vegetables destroys their antiscorbutic properties, and he attributed the occasional occurrence of scurvy in the army to the cooks, who sometimes over-boiled the stew of which fresh vegetables formed a constituent. He had found cases of scurvy in pigs in Aberdeenshire. Their food, he supposed, had been cooked in the usual Scottish way, for four or five hours, thus destroying the antiscorbutic properties of swedes and potatoes. When given fresh swedes and potatoes, in addition to their other food, they had in four weeks' time, become quite well, and two months afterwards fetched full market prices. Dr. Plimmer said that he had recently seen a number of poultry suffering from polyneuritis and showed a lantern slide of a Leghorn cock paralysed in the legs, which had lost its "voice." He then produced from a portable coop a very robust-looking white Leghorn cock, which crowed lustily, flapped its wings, and flew through the lecture-hall. This was the former victim, now cured by the administration of water-soluble B food substance.

Appointments.

Successful applicants for vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANCET *Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication.*

Allen, C. H., M.B., F.R.C.S. Edin., has been appointed an additional general Medical Referee under the Workmen's Compensation Act for County Court Circuit No. 18.

Sandiland, E. L., M.B., B.S. Lond., D.P.H., Medical Superintendent to the Kent County Sanatorium, Lenham.

Vacancies.

For further information refer to the advertisement columns.

Bath, Royal United Hospital.—H.S. and H.P. £200 each.

Birkenhead and Wirral Children's Hospital, Woodchurch-road.—H.S. £150.

West Riding County Council.—Dist. Tuberc. O.'s. £600. Asst. M.O. (Res.). £325. Sch. Oculist. £600. Sch. Med. Inspectors. £500.

THE Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at Chipping Campden, Kilbride, Moville, Tattenhall, Wansford, and Warminster.

is a creature of habits; the modern worker tends to demand interests. Whether work be carried out mechanically through mere habit, or purposefully through definite interests, the appropriate attitude has to be maintained. To maintain an attitude favourable to a given work means to repress the development of other attitudes less favourable or unfavourable for that work. In other words, all conflicting mental systems must be held in check. Untoward thoughts must be inhibited, and physical work is necessarily expended in such inhibition or repression. At first, whether through habit or interest, this process of repression or inhibition is unconscious. Later it can only continue by voluntary effort. Finally, voluntary effort becomes fatigued, and boredom, now already on the scene, makes its presence more and more felt as interest has waned. Distracting thoughts are no longer under control. The mental system tends to disorder. In the wake of contested boredom follows worry, which is inevitably accompanied by a wasteful dissipation of mental energy; and it must be remembered that whatever be its origin, no cause of mental inefficiency is so potent as worry.

SWISS MEDICAL DIRECTORY.

THE *Annuaire Médical Suisse* for 1920, published by the Société Suisse d'Edition (Lausanne, 4 Jumelles) at Fr.4.50, is in its seventh edition. Names of doctors, dentists, pharmacists, and veterinarians are given, first arranged topographically and then in alphabetical order. Then follow the federal and cantonal sanitary authorities and an excerpt of the regulations governing the professional examinations. A list of mineral and thermal waters concludes a business-like little directory which will be found of service by any medical men who send patients to Switzerland.

A MEDICAL CANDIDATE.

POLITICAL feeling in South Africa is running high in view of the pending General Election. A correspondent writes that after the nomination of Dr. J. A. Raubenheimer by the South African Party, leading Nationalists among his patients approached the doctor and asked for their accounts, which were forthwith settled. Dr. Raubenheimer, who is a very popular practitioner, is alleged to have informed these patients after this episode that on no account would he attend them if summoned for illness.

BOOKS OF REFERENCE.

AMONG handy books of reference "*Hazell*" holds an honoured place and the volume for 1921 (being the 36th annual issue) of the New Hazell Annual and Almanack, edited by T. A. Ingram, M.A., LL.D. (London: Henry Frowde and Hodder and Stoughton. Pp. lvi. + 823. Price 7s. 6d.) appears betimes. It contains all the usual topical information concerning the nations of the world, some 100 pages of space having been saved by omission or abridgement of certain summaries at the end. We miss the interesting little section on "Medicine in 1919," which had evidently been prepared with care and discretion. Among the current features are the texts of the Covenant of the League of Nations and Labour's Charter under the League, an account of the Peace Treaty negotiations, statistics of the casualties in men and officers during the war, a baronetage and knightage, and particulars in regard to the Ministry of Health, as well as of societies and institutions whose objects in one way or another are to promote the physical welfare of the country. Astronomical and everyday information common to almanacks also find a place.

HOW DOCTORS DIE IN AMERICA.

THE New Year issue of the *Journal of the A.M.A.* contains the usual prompt analysis of the deaths of medical men in the United States of America during the preceding year. General diseases accounted for 257 deaths, diseases of the nervous system 271, diseases of the circulatory system 401, diseases of the respiratory system 266, diseases of the digestive system 70, diseases of the genito-urinary system [illegible], senility 77, suicide 32, accidents 102, homicide 14, and sequels of surgical operations 74. The most frequent individual causes of death were: Organic heart disease [illegible], cerebral hæmorrhage 211, pneumonia 156, nephritis and uræmia 142, malignant tumours 91, tuberculosis 59, angina pectoris 50, pneumonia-influenza 37, and arteriosclerosis 35. The causes and distribution of the 102 deaths from accident were: automobile, 27; automobile-railway grade crossing, 22; [illegible], 9; falls, 8; firearms, 7; drowning, 6; railway and street car, each, 5; asphyxia, 3; [illegible] and burns, each, 2; crushing, 1, and other accidents, 5. The 32 physicians who ended their lives by suicide selected these methods: firearms, 15; poisons, 7; cutting instruments, 3; strangulation, 2; jumping from [illegible] and drowning each, 1. Of the 14 homicides, [illegible] by firearms.

The Hunterian Lecture

No. LIBRARY

COLECTOMY.

Delivered at a Meeting of the Hunterian Society on Jan. 19th, 1921,

BY SIR W. ARBUTHNOT LANE, BART.,
M.S. LOND., F.R.C.S. ENG.,
CONSULTING SURGEON, GUY'S HOSPITAL, ETC.

IN this paper I hope to indicate the purpose of colectomy, the risks associated with it, and the complications that may arise after its performance. I will also call attention to the conditions which are benefited by this operation.

CHRONIC INTESTINAL STASIS.

In the short time at my disposal it will be impossible to recapitulate, however briefly, what I have written during the last 20 years on chronic intestinal stasis, its causation and symptoms, since the subject has developed so much in that time. I have attempted to summarise it in two recent papers published in THE LANCET, The Evolution of Disease[1] and The Operative Treatment of Cancer of the Colon,[2] to which I would refer you for further details. Suffice it to say that the delay in the passage of the fæcal matter, which produces its earliest result in the pelvic colon, extends along the length of the large bowel and tends to distend, dilate, and prolapse the cæcum and the ascending and transverse segments of the colon.

In consequence of the stagnation of the contents of the large bowel mechanical changes take place in the rest of the gastro-intestinal tract. Associated with these there is an ascending infection of the originally sterile contents of the small intestine and duodenum, which results in a contamination of the food-supply of the individual by micro-organisms. The products resulting from the fouling of the intestinal chyme, the material from which the body obtains its nourishment, are absorbed into the circulation. A proportion escapes conversion or excretion in the liver and kidneys and produces a degenerative change in every tissue. This deleterious matter also throws an excessive strain upon the excretory and ductless glands, so that the latter undergo variations in structure and function. Organisms such as *Bacillus coli*, &c., may get into the blood stream. This condition, due to infection of the contents of the small intestine, I called intestinal auto-intoxication, which term, perhaps, describes it as well as any other. Too much importance cannot be attached to this result of chronic intestinal stasis, since upon it directly or indirectly depend the innumerable changes which take place in the body and which are called diseases. It is the disastrous consequence of simple stasis. The degenerative changes in such organs as the breast, ovary, uterus, pancreas, &c., are very liable to terminate in cancer.

I have fully described the effects of the toxins and organisms on the fat, muscle, cerebro-spinal system, circulatory system, thyroid, adrenal, pituitary, skin, uterus, ovaries, testes, kidneys, liver, and pancreas. The effect on these several structures is the result of the septic infection of the blood stream in which they are bathed and from which their component cells derive their nutrition. In the case of the liver and pancreas there is an added source of infection through the ducts of these organs.

MEDICAL TREATMENT.

Up to a certain point medical treatment may avail to stem the degree and effects of auto-intoxication. It consists in efforts to empty the large bowel by purgatives or by enemas, massage, electricity, and exercise; to sterilise the contents of the small intestine by the use of organisms, vaccines, and antiseptic drugs which exert an inhibitory or deleterious effect on the microbes which have invaded the small intestine, such as the Bulgarian bacillus, mercury, arsenic, iron, &c.; by giving such foods as break up easily and rapidly, and either remain in the small intestine for a short time or do not decompose if retained for an abnormal period; by avoiding all such forms of meat as take long to be digested, and so favour their decomposition; and by the use of large quantities of water which flush the intestinal tract and carry away effete products by the kidneys, &c. In the so-called water cures the essential factor in any success that may attend the treatment is the flushing of the intestine and circulation by the water, the salts playing a very secondary part.

One must realise that stasis commences early in the life-time of the individual. It is probable that when the napkin is discarded, and the infant is habituated to a single daily action, the pelvic colon, being unable to accommodate the amount of nourishment taken during 24 hours, gradually elongates or becomes fixed and obstructed by the formation of controlling bands or membranes. Once a mechanical disability to the evacuation of the fæcal contents arises in the end of the large bowel the sequence of events is inevitably progressive. Its rapidity varies with the vitality of the individual. In treating a case of stasis, whether chiefly mechanical or toxic in character, every means should be adopted as early in life as possible to stay the progress of the changes by diet, the more frequent evacuation of the bowel by the use of paraffin, by rest at suitable intervals, &c.

Indications for Colectomy.

If the symptoms are accentuated by bands, inflammation of the appendix, control of the ileal effluent by an anchored appendix, by obstruction at the duodeno-jejunal junction, or by the presence of duodenal or gastric ulcers surgical measures must be resorted to at once.

When all these means have failed to stay the progress of the disease what is to be done? It is absolutely necessary that the infection of the contents of the small intestine be eliminated, and while the obstruction to the free flow of the ileal contents exists in the form of a mechanically disabled and inflamed large intestine there is nothing left but to remove that diseased and obstructing structure. It is not an operation that should be undertaken lightly; it can only be considered when all other means have proved unsuccessful. The choice is between folding one's hands and watching or taking action which if successful affords the patient incalculable advantages. The necessity for this action is frequently accentuated by the fact that the lowered vitality of the tissues and the diminution of their resisting power make them a prey to organisms which may invade and obtain a foothold in them. It would appear that the organs or tissues most liable to degenerative change as well as the resisting power to the several kinds of organisms are not the same in different individuals, families, and groups, and vary in the same individual at different ages. While in the child the lymphatic tissue of the naso-pharynx is very prone to suffer, later in life the gums form a common seat of infection. The condition of the gums which is called pyorrhœa is perhaps the most frequent and obvious, as well as being one of the most important, examples of infection of devitalised tissues by organisms, not in itself necessarily calling for other than local treatment. Pyorrhœa when fully developed becomes, as do many other secondary inflammations, an additional source of infection of the system, and may seriously aggravate existing symptoms or be the source of new diseases. This is sometimes so marked that casual observers have been led to regard pyorrhœa as the primary factor in producing many diseases, and even in determining the changes in the gastro-intestinal tract. This is not the case, though, as I have indicated, pyorrhœa may become a secondary factor of considerable importance and may aggravate existing infection of the intestinal contents.

DISEASES ORIGINATING IN AUTO-INTOXICATION.

It is difficult to limit the number of diseases which depend directly or indirectly for their existence on auto-intoxication, for some of which colectomy may be performed with great benefit.

---

[1] THE LANCET, 1919, ii., p. 1117.

[2] THE LANCET, 1920, ii., p. 1184.

The most frequent and obvious are rheumatoid arthritis, Still's disease, tubercle, Bright's disease, non-specific arteritis obliterans, Raynaud's disease, Addison's disease, melancholia, dementia præcox, dis- seminated sclerosis, pernicious anæmia, paralysis agitans, asthma, atheroma, infective endocarditis, angina pectoris, many forms of skin disease as pruritus, &c., ulcerative colitis, exophthalmic goitre, adenoma of the thyroid, microbic cyanosis, diabetes mellitus, and neuralgias. There are a host of other conditions which I might enumerate, cancer being the last and not the least important; but for cancer colectomy is useless except when the growth involves the large bowe primarily.

As regards surgical measures, assuming that an ileal kink or a controlling appendix does not exist, or has already been dealt with, that any definite obstruction of the large bowel by band has been divided, and that any angulation at the duodeno-jejunal junction sufficiently acute to necessitate a gastro-enterostomy has been treated, what means have we got of removing this obstruction to the ileal effluent? To deal with this effectually one must bear in mind that it starts primarily in the elongated and dilated pelvic colon, it may be accentuated or not at the last kink, it extends along the iliac, descending, and transverse colon. and is often aggravated by spasm consequent on an inflammation of the mucous membrane, commonly called colitis. The cæcum and ascending colon are usually distended with the intestinal contents, dammed back by this obstruction, whether produced by constriction by acquired bands or by great elongation of the bowel with associated inflammation of its mucous lining producing spasm of the muscle wall, while the dilated and prolapsed cæcum, falling to the bottom of the pelvis, may become so displaced as to twist and obstruct the terminal ileum, as Dr. A. C. Jordan has shown so clearly. While colectomy is urgently called for in many conditions which result directly from intestinal auto-intoxication, it is even more imperatively demanded in the case of those diseases which can only develop in a subject in whom the vitality and resisting power of the tissues have been sufficiently depreciated by stasis to allow of their being invaded and occupied by deleterious organisms.

METHOD OF OPERATION.

The method I employ in performing colectomy is the division of the ileum at a convenient point several inches proximal to its termination and the removal of the large bowel, leaving only enough pelvic colon to permit of a perfect end-to-end junction with the extremity of the ileum.

In most cases—more frequently in women, in whom the acquired bands are not usually as well developed as in men—this operation offers no special difficulty, but if the acquired membranes are strong it is important that the surgeon should be perfectly familiar with their arrangement, especially about the splenic flexure. I believe it is due to the trouble that many have experienced in dealing with this flexure that recourse has been had to the futile operation of removing the cæcum, ascending, and portion of the transverse colon. Many years ago I employed this method of partial resection, but discarded it at once on recognising its insufficiency to relieve the patient of the obstruction in the second half of the large bowel, for the relief of which an operation was performed.

There is one practical point of great interest in connexion with these operations. In the earlier colectomies I divided the pelvic colon at a point that enabled me to form a lateral anastomosis between the closed ends of the ileum and colon. The disappearance of symptoms followed this operation very rapidly, and the patient soon got quite well. After an interval of months or years the symptoms occasionally recurred, to my great disappointment. As an infection of the food-supply was evidently the original factor in the development of the particular disease I again explored [illegible] abdomen, and found that besides a considerable [illegible] of the residual pelvic colon, due to its [illegible] frequent evacuation, extensions of the [illegible] ileum had grown upwards and downwards, and that in these diverticula the contents of the bowel collected, decomposed, and interfered with the free effluent from the ileum. On cutting out this junction and taking away the excess of pelvic colon, together with the protruding large dilated ends of the colon and ileum, symptoms disappeared as before. This decided me to give up establishing a lateral junction and to put the divided extremity of the ileum directly into that of the pelvic colon. There is no difficulty whatever in connecting the end of the ileum with that of the pelvic colon, however different their calibres, if the sutures are radiated in such a manner as to include correct proportions of the circumference of each bowel. It is not necessary, nor is it advantageous, to attempt to increase the calibre of the bowel by splitting it or cutting it obliquely, as has been recommended. Such methods are liable to alter the relations of the long axes of the segments of bowel to one another, and to favour angulation and obstruction at the junction.

Complications following Colectomy.

A case of Still's disease on which I operated provided an excellent illustration of some of the complications which may follow a colectomy. It also proved the necessity of watching for a recurrence of any symptom and dealing with it at the earliest possible moment. It represents the kind of case in which colectomy in inexperienced hands may not ensure the permanent cure that should fairly be expected from it. The first operation undertaken in the case was an ileo-colostomy. It was followed by a freedom from symptoms for nearly nine months, after which some evidences of the disease reappeared. A colectomy was then performed. It was imperfect in the light of our present experience, since a lateral junction, not an end-to-end connexion, was effected. It gave a complete freedom from any joint infection for six years. The recurrence of symptoms which then appeared were met successfully by perfecting the colectomy, the dilated ends with the lateral junction and a length of the recently elongated pelvic colon being excised and replaced by an end-to-end junction; the importance of the frequent evacuation of the bowel was impressed on the patient.

I have referred to this case to indicate some of the complications which may arise in connexion with colectomy. In a certain small proportion of colectomies that escape from observation for a considerable time symptoms of obstruction or a recurrence of the disease may occasionally occur. I refer to such conditions as exophthalmic goitre, rheumatoid arthritis, epileptiform tic, Still's disease, Raynaud's disease, and some others in which, after an apparently magical cure, a relaps may take place months or years after; much disappointment may then be experienced, the patient having been delighted with the effect of the colectomy.

The two complications which are liable to affect thi operation disadvantageously are obstruction from inflammatory adhesions and obstruction from excessive elongation of the pelvic colon. The latter is avoided by evacuating the residual colon three times a day. The former can only be met by operative interference. The chief immediate risks of the operation are hæmorrhage, damage to bowel, and possibly shock. The former is most liable to take place in a fat patient, as a vessel embedded in fat may bleed after an interval of time, even if the ligature surrounding it appears to be very tight. This accident may be avoided by forcibly compressing the mesentery before the ligature is applied. Care must be taken to avoid damage to the duodenum, which in many cases is intimately associated with the ascending colon. Precautions are also necessary in ligaturing the mesentery of the colon where it is short and tight. It is quite possible to include a portion of the large bowel in the ligature unless care is taken to avoid such an accident, especially in the neighbourhood of the splenic flexure.

Avoidance of Shock by Saline.

Of course, if a patient is in an almost moribund condition at the time of the operation death may ensue very soon after, but this has not occurred in my practice. The complete freedom from shock is due, I believe, to the fact that ever since I saw L. C. Wooldridge's experiment of replacing the loss of blood by normal saline I have in all these operations introduced six or seven pints of this solution into the axillæ, starting the injection as soon as possible after the commencement of the anæsthetic. In the earliest cases the fluid was injected directly into the venous circulation. Wooldridge kept no record of this experiment, which I published after his death in THE LANCET under the heading of a Surgical Tribute to the late Dr. Wooldridge.[3] The advantage which humanity has derived from this manifestation of Wooldridge's remarkable genius is almost incalculable. His research completely negatived the conclusion arrived at by Professor Schäfer in the investigation on transfusion he carried out at the request of the Obstetrical Society of London.

Stimulation of Intestines after Operation.

An accident which may arise in effecting the junction of the end of the ileum to the pelvic colon is a rotation of the end of the ileum on its axis. This may result in the formation of a twist of the end of the ileum and in its partial obstruction. It also renders the closure of the interval between the mesenteries of the ileum and pelvic colon difficult and possibly imperfect.

It must be remembered that the vast majority of colectomies are performed for the direct results of stasis of the simple toxic variety or for those in which the superadded infection by organisms is the prominent feature. The muscles generally, and the muscular coat of the small intestine especially, are thin, atrophied, and sluggish, so that this portion of the bowel lies inert and flaccid for a long period after the large bowel has been removed, and usually requires to be stimulated into activity by drugs. To meet this requirement a little castor oil or phenolphthalein should be added to the paraffin, which is administered as soon as possible after the operation. This tends to prevent stagnation of the intestines by stimulating them to vigorous action, and so to obviate the formation of inflammatory adhesions.

If there is any surface of the surrounding abdominal wall which has been deprived of its normal smooth peritoneal lining the inactive bowel is very likely to form adhesions to it, and sooner or later obstruction may result, sometimes after a long interval of months or years. The development of these inflammatory adhesions can only be avoided by the most scrupulous care on the part of the surgeon to avoid ligaturing large masses of mesentery or omentum, to cover with peritoneum all areas deprived of its protection, and to commence stimulating the intestines to act as soon as possible after the operation by means of paraffin and other agents.

Difficulties Occasioned by Previous Operations.

A great difficulty the surgeon not infrequently experiences in colectomy is that the patient may have already undergone many operations—appendicostomy, cæcostomy, suturing the cæcum to the iliac fossa, resection of part of the transverse colon, shortening of mesenteries, fixation of the omentum to the abdominal wall, and a host of other procedures—all of which render the accurate apposition of the edges of peritoneum very difficult indeed, and increase enormously the risk of the formation of adhesions, which constitute one of the most troublesome complications met with. Should obstruction result from this development it is important that the surgeon should act promptly, and should deal with them as effectually as possible. Symptoms of obstruction are most liable to develop after the removal of the tube from the rectum.

I recently excised with complete success the colon from a man who had been seen by more than 50 surgeons in different parts of Canada and the States, and who had had 16 abdominal operations, including 4 lateral anastomoses. His condition was regarded as inoperable. In dealing with very complicated cases it is well to remember that life may be carried on in perfect comfort with only a short length of small intestine.

RESULTS OF IMPERFECT OPERATIVE PROCEDURE.

Diarrhœa following the operation is due to a partial obstruction, the frequent fluid motions being of the nature of an overflow, as in the analogous case of a leaking, over-distended bladder. This is frequently due to the surgeon not having taken sufficient care to avoid axial rotation of the end of the ileum, or to the imperfect union of the cut edges of the mesentery of the end of the ileum and of the pelvic colon, or to their separation subsequent to the operation allowing the intestines to prolapse through the interval and causing torsion of the terminal ileum. These mesenteries may become separated weeks or months after the operation for no very obvious reason.

The recurrence of superadded infections is usually due either to imperfect operative procedure or to the persistence of organisms in the wall of the small intestines which have not been destroyed by treatment after the operation, or more usually to the subsequent enormous elongation of the residual pelvic colon due to its over-distension from insufficiently frequent evacuation of its contents. The last condition arises because the patient will insist on having only one daily action, so that the intake of 24 hours is retained in the residual portion of the pelvic colon, which comprises only a fraction of the whole large intestine. Consequently it elongates, puddles in the pelvis, and obstructs the effluent from the ileum as effectually as it did before the large bulk of an elongated pelvic colon had been removed by a colectomy.

Many of the organisms that produce these diseases seem to invade and remain latent in the mucous membrane of the small intestine, and while they are enormously depleted in number by the freeing of the ileal effluent by the colectomy, they readily extend into and infect the contents of the ileum when stagnation again results from the subsequent development of obstruction. Fortunately, this only takes place in a small proportion of colectomies, yet the number is quite large enough to make it necessary to watch the progress of every case for some time and to endeavour to eliminate any residual organisms by drugs, vaccines, and diet. This is particularly called for when the residual pelvic colon is infected, as it may be in the case of dysentery and ulcerative colitis. Dr. N. Mutch lays great stress on the importance of the use of vaccines, &c., after some cases of colectomy. The surgeon must not consider the patient free from the possibility of recurrence till many years have elapsed, however extraordinary and remarkable may be the immediate success of the operation.

I think I have indicated clearly the causes of the failure and disappointment which occasionally exist after colectomy, and it is only by bearing them in mind and by taking every possible precaution to avoid them that the surgeon can hope to ensure a successful result. It is obvious that colectomy cannot be followed by equally beneficial results in many of the diseases which I have enumerated for the reason that much of the damage already done at the time of the [illegible] irremediable. For instance, teeth removed [illegible] rhœa cannot be replaced; changes in the [illegible] have resulted in permanent damage; [illegible] deformities, disabilities of rheumatoid arthri[illegible] bony ankylosis of joints, are unaffected by [illegible] tion; and the organ or articulation [illegible] tubercle cannot be restored to its normal st[illegible] usefulness, and so on. Yet in spite of all this [illegible] innumerable changes resulting directly and [illegible] from stasis which recover to an extent that [illegible] sight would seem quite impossible. The [illegible] aspect of it is the extraordinary rapidity with [illegible] they ensue in many conditions. In some the [illegible] almost instantaneous, while in others the sympt[illegible] disappear slowly.

CONCLUSION.

The mortality of the operation must vary largely w[illegible] the kind of case on which the surgeon operates. [illegible] man will confine the operation only to such as [illegible] appear to be what are called "good surgical risks"; another is prepared to interfere in cases of a very

---

[3] THE LANCET, 1891, ii., p. 626.

The most frequent and obvious are rheumatoid arthritis, Still's disease, tubercle, Bright's disease, non-specific arteritis obliterans, Raynaud's disease, Addison's disease, melancholia, dementia præcox, disseminated sclerosis, pernicious anæmia, paralysis agitans, asthma, atheroma, infective endocarditis, angina pectoris, many forms of skin disease as pruritus, &c., ulcerative colitis, exophthalmic goitre, adenoma of the thyroid, microbic cyanosis, diabetes mellitus, and neuralgias. There are a host of other conditions which I might enumerate, cancer being the last and not the least important; but for cancer colectomy is useless except when the growth involves the large bowel primarily.

As regards surgical measures, assuming that an ileal kink or a controlling appendix does not exist, or has already been dealt with, that any definite obstruction of the large bowel by band has been divided, and that any angulation at the duodeno-jejunal junction sufficiently acute to necessitate a gastro-enterostomy has been treated, what means have we got of removing this obstruction to the ileal effluent? To deal with this effectually one must bear in mind that it starts primarily in the elongated and dilated pelvic colon, it may be accentuated or not at the last kink, it extends along the iliac, descending, and transverse colon, and is often aggravated by spasm consequent on an inflammation of the mucous membrane, commonly called colitis. The cæcum and ascending colon are usually distended with the intestinal contents, dammed back by this obstruction, whether produced by constriction by acquired bands or by great elongation of the bowel with associated inflammation of its mucous lining producing spasm of the muscle wall, while the dilated and prolapsed cæcum, falling to the bottom of the pelvis, may become so displaced as to twist and obstruct the terminal ileum, as Dr. A. C. Jordan has shown so clearly. While colectomy is urgently called for in many conditions which result directly from intestinal auto-intoxication, it is even more imperatively demanded in the case of those diseases which can only develop in a subject in whom the vitality and resisting power of the tissues have been sufficiently depreciated by stasis to allow of their being invaded and occupied by deleterious organisms.

METHOD OF OPERATION.

The method I employ in performing colectomy is the division of the ileum at a convenient point several inches proximal to its termination and the removal of the large bowel, leaving only enough pelvic colon to permit of a perfect end-to-end junction with the extremity of the ileum.

In most cases—more frequently in women, in whom the acquired bands are not usually as well developed as in men—this operation offers no special difficulty, but if the acquired membranes are strong it is important that the surgeon should be perfectly familiar with their arrangement, especially about the splenic flexure. I believe it is due to the trouble that many have experienced in dealing with this flexure that recourse has been had to the futile operation of removing the cæcum, ascending, and portion of the transverse colon. Many years ago I employed this method of partial resection, but discarded it at once on recognising its inefficiency to relieve the patient of the obstruction in the second half of the large bowel, for the relief of which an operation was performed.

There is one practical point of great interest in connexion with these operations. In the earlier colectomies I divided the pelvic colon at a point that enabled me to form a lateral anastomosis between the closed ends of the ileum and colon. The disappearance of symptoms followed this operation very rapidly, and the patient soon got quite well. After an interval of months or years the symptoms occasionally recurred, to my great disappointment. As an infection of the food-supply was evidently the original factor in the development of the particular disease I again explored the abdomen, and found that besides a considerable elongation of the residual pelvic colon, due to its insufficiently frequent evacuation, extensions of the colon and ileum had grown upwards and downwards, and that in these diverticula the contents of the bowel collected, decomposed, and interfered with the free effluent from the ileum. On cutting out this junction and taking away the excess of pelvic colon, together with the protruding large dilated ends of the colon and ileum, symptoms disappeared as before. This decided me to give up establishing a lateral junction and to put the divided extremity of the ileum directly into that of the pelvic colon. There is no difficulty whatever in connecting the end of the ileum with that of the pelvic colon, however different their calibres, if the sutures are radiated in such a manner as to include correct proportions of the circumference of each bowel. It is not necessary, nor is it advantageous, to attempt to increase the calibre of the bowel by splitting it or cutting it obliquely, as has been recommended. Such methods are liable to alter the relations of the long axes of the segments of bowel to one another, and to favour angulation and obstruction at the junction.

Complications following Colectomy.

A case of Still's disease on which I operated provided an excellent illustration of some of the complications which may follow a colectomy. It also proved the necessity of watching for a recurrence of any symptom and dealing with it at the earliest possible moment. It represents the kind of case in which colectomy in inexperienced hands may not ensure the permanent cure that should fairly be expected from it. The first operation undertaken in the case was an ileo-colostomy. It was followed by a freedom from symptoms for nearly nine months, after which some evidences of the disease reappeared. A colectomy was then performed. It was imperfect in the light of our present experience, since a lateral junction, not an end-to-end connexion, was effected. It gave a complete freedom from any joint infection for six years. The recurrence of symptoms which then appeared were met successfully by perfecting the colectomy, the dilated ends with the lateral junction and a length of the recently elongated pelvic colon being excised and replaced by an end-to-end junction; the importance of the frequent evacuation of the bowel was impressed on the patient.

I have referred to this case to indicate some of the complications which may arise in connexion with colectomy. In a certain small proportion of colectomies that escape from observation for a considerable time symptoms of obstruction or a recurrence of the disease may occasionally occur. I refer to such conditions as exophthalmic goitre, rheumatoid arthritis, epileptiform tic, Still's disease, Raynaud's disease, and some others in which, after an apparently magical cure, a relapse may take place months or years after; much disappointment may then be experienced, the patient having been delighted with the effect of the colectomy.

The two complications which are liable to affect this operation disadvantageously are obstruction from inflammatory adhesions and obstruction from excessive elongation of the pelvic colon. The latter is avoided by evacuating the residual colon three times a day. The former can only be met by operative interference. The chief immediate risks of the operation are hæmorrhage, damage to bowel, and possibly shock. The former is most liable to take place in a fat patient, as a vessel embedded in fat may bleed after an interval of time, even if the ligature surrounding it appears to be very tight. This accident may be avoided by forcibly compressing the mesentery before the ligature is applied. Care must be taken to avoid damage to the duodenum, which in many cases is intimately associated with the ascending colon. Precautions are also necessary in ligaturing the mesentery of the colon where it is short and tight. It is quite possible to include a portion of the large bowel in the ligature unless care is taken to avoid such an accident, especially in the neighbourhood of the splenic flexure.

Avoidance of Shock by Saline.

Of course, if a patient is in an almost moribund condition at the time of the operation death may ensue very soon after, but this has not occurred in my practice. The complete freedom from shock is due, I believe, to the fact that ever since I saw L. C. Wooldridge's experiment of replacing the loss of blood by normal saline I have in all these operations introduced six or seven pints of this solution into the axillæ, *starting the injection as soon as possible after the* commencement of the anæsthetic. In the earliest cases the fluid was injected directly into the venous circulation. Wooldridge kept no record of this experiment, which I published after his death in THE LANCET under the heading of a Surgical Tribute to the late Dr. Wooldridge.[3] The advantage which humanity has derived from this manifestation of Wooldridge's remarkable genius is almost incalculable. His research completely negatived the conclusion arrived at by *Professor Schäfer in the investigation on transfusion* he carried out at the request of the Obstetrical Society of London.

Stimulation of Intestines after Operation.

An accident which may arise in effecting the junction of the end of the ileum to the pelvic colon is a rotation of the end of the ileum on its axis. This may result in the formation of a twist of the end of the ileum and in its partial obstruction. It also renders the closure of the interval between the mesenteries of the ileum and pelvic colon difficult and possibly imperfect.

It must be remembered that the vast majority of colectomies are performed for the direct results of stasis of the simple toxic variety or for those in which the superadded infection by organisms is the prominent feature. The muscles generally, and the muscular coat of the small intestine especially, are thin, atrophied, and sluggish, so that this portion of the bowel lies inert and flaccid for a long period after the large bowel has been removed, and usually requires to be stimulated into activity by drugs. To meet this requirement a little castor oil or phenolphthalein should be added to the paraffin, which is administered as soon as possible after the operation. This tends to prevent stagnation of the intestines by stimulating them to vigorous action, and so to obviate the formation of inflammatory adhesions.

If there is any surface of the surrounding abdominal wall which has been deprived of its normal smooth peritoneal lining the inactive bowel is very likely to form adhesions to it, and sooner or later obstruction may result, sometimes after a long interval of months or years. *The development of these inflammatory* adhesions can only be avoided by the most scrupulous care on the part of the surgeon to avoid ligaturing large masses of mesentery or omentum, to cover with peritoneum all areas deprived of its protection, and to commence stimulating the intestines to act as soon as possible after the operation by means of paraffin and other agents.

Difficulties Occasioned by Previous Operations.

A great difficulty the surgeon not infrequently experiences in colectomy is that the patient may have already undergone many operations—appendicostomy, cæcostomy, suturing the cæcum to the iliac fossa, resection of part of the transverse colon, shortening of mesenteries, fixation of the omentum to the abdominal wall, and a host of other procedures—all of which render the accurate apposition of the edges of peritoneum very difficult indeed, and increase enormously the risk of the formation of adhesions, which constitute one of the most troublesome complications met with. Should obstruction result from this development it is important that the surgeon should act promptly, and should deal with them as effectually as possible. Symptoms of obstruction are most liable to develop after the removal of the tube from the rectum.

I recently excised with complete success the colon from a man who had been seen by more than 50 surgeons in different parts of Canada and the States, and who had had 16 abdominal operations, including 4 lateral anastomoses. His condition was regarded as inoperable. In dealing with very complicated cases it is well to remember that life may be carried on in perfect comfort with *only a short length of small* intestine.

RESULTS OF IMPERFECT OPERATIVE PROCEDURE.

Diarrhœa following the operation is due to a partial obstruction, the frequent fluid motions being of the nature of an overflow, as in the analogous case of a leaking, over-distended bladder. This is frequently due to the surgeon not having taken sufficient care to avoid axial rotation of the end of the ileum, or to the imperfect union of the cut edges of the mesentery of *the end of the ileum and of the pelvic colon, or to their* separation subsequent to the operation allowing the intestines to prolapse through the interval and causing torsion of the terminal ileum. *These mesenteries may* become separated weeks or months after the operation for no very obvious reason.

The recurrence of superadded infections is usually due either to imperfect operative procedure or to the persistence of organisms in the wall of the small intestines which have not been destroyed by treatment after the operation, or more usually to the subsequent enormous elongation of the residual pelvic colon due to its over-distension from insufficiently frequent evacuation of its contents. The last condition arises because the patient will insist on having only one daily action, so that the intake of 24 hours is retained in the residual portion of the pelvic colon, which comprises only a fraction of the whole large intestine. Consequently it elongates, puddles in the pelvis, and obstructs the effluent from the ileum as effectually as it did before the large bulk of an elongated pelvic colon had been removed by a colectomy.

Many of the organisms that produce these diseases seem to invade and remain latent in the mucous membrane of the small intestine, and while they are enormously depleted in number by the freeing of the ileal effluent by the colectomy, they readily extend into and infect the contents of the ileum when stagnation again results from the subsequent development of obstruction. Fortunately, this only takes place in a small proportion of colectomies, yet the number is quite large enough to make it necessary to watch the progress of every case for some time and to endeavour to eliminate any residual organisms by drugs, vaccines, and diet. This is particularly called for when the residual pelvic colon is infected, as it may be in the *case of dysentery and ulcerative colitis. Dr. N. Mutch* lays great stress on the importance of the use of vaccines, &c., after some cases of colectomy. The surgeon must not consider the patient free from the possibility of recurrence till many years have elapsed, however extraordinary and remarkable may be the immediate success of the operation.

I think I have indicated clearly the causes of the failure and disappointment which occasionally exist after colectomy, and it is only by bearing them in mind and by taking every possible precaution to avoid them that the surgeon can hope to ensure a successful result. It is obvious that colectomy cannot be followed by equally beneficial results in many of the diseases which I have enumerated for the reason that much of the damage already done at the time of the operation is irremediable. For instance, teeth removed for pyor*rhœa cannot be replaced; changes in the spinal cord* have resulted in permanent damage; the severe deformities, disabilities of rheumatoid arthritis due to bony ankylosis of joints, are unaffected by the operation; and the organ or articulation disorganised by tubercle cannot be restored to its normal structure and usefulness, and so on. Yet in spite of all this there are innumerable changes resulting directly and indirectly from stasis which recover to an extent that at first sight would seem quite impossible. The strangest aspect of it is the extraordinary rapidity with which they ensue in many conditions. In some the change is almost instantaneous, while in others the symptoms disappear slowly.

CONCLUSION.

The mortality of the operation must vary largely with *the kind of case on which the surgeon operates.* One man will confine the operation only to such as would appear to be what are called "good surgical risks";

serious nature, realising that with death or prolonged misery facing the sufferer he must take his courage in his hands and do what he conscientiously considers to be the best for his patients, although it may not coincide with the good effect he hopes to produce by favourable statistics. At the present time colectomy is performed very generally in many parts of the world. Such an advanced and progressive surgical community as the Argentine, for instance, is fortunate in possessing both Dr. Jose Arce, the professor of clinical surgery of the Faculty of Medicine of Buenos Ayres, and Dr. Artemio Zeno, the professor of surgery in the Litoral University of Rosario, who tell me that they have done very many colectomies, and are continuing to do them in increasing numbers with a very small mortality. Even in England, where progress is slow but equally sure, I find that many surgeons are doing this operation with great advantage to their patients.

Perhaps even more important than the operation is the wider knowledge of chronic intestinal stasis and of the conditions of which stasis is a necessary antecedent, together with their medical treatment, which surgical measures have tended to develop. Not its least result has been to make medical men concentrate their attention on this most important and very comprehensive subject.

LEGG'S OR PERTHES'S DISEASE.

THE DIFFERENTIAL DIAGNOSIS OF AFFECTIONS AT THE HIP IN CHILDREN.[1]

BY H. BUCKLEY RODERICK, O.B.E., M.A., M.CH., M.D. CANTAB.,

UNIVERSITY DEMONSTRATOR OF SURGERY AND ASSISTANT SURGEON, ADDENBROOKE'S HOSPITAL, CAMBRIDGE.

WHEN a child who complains of pain in the hip and shows a limp on walking is brought for advice the suggestion of "hip disease" naturally occurs to us. Tuberculous disease is at once the commonest and gravest affection of the hip, necessitating early diagnosis and treatment if the functional utility of the joint is to be restored. It is always well, therefore, first to exclude this disease before proceeding to examine for other conditions. Throughout life the region of the hip is liable to such a variety of diseases, deformities, and injuries that at any age a most careful, methodical, and exhaustive examination is essential for an accurate diagnosis. On account of its inaccessibility both to visual and manual examination the hip-joint, of all joints in the body, presents the greatest difficulty. Without skiagraphy our conclusions, based largely upon indirect evidence, call forth the utmost diagnostic resource of the examiner. True, the advent of X rays has rendered the task more easy and proves of inestimable value in confirming or disproving our deductions, but complete reliance on such diagnosis without careful and methodical physical examination will lead, sooner or later, to serious error.

Limping.

The late Sir George Humphry's dictum that the human foot was God's last and most perfect work might very well be extended to include the whole mechanism of walking, which, being so intricate and perfect, like all complicated machinery, is very easily thrown out of gear by very slight causes, such, for instance, as a small corn on the little toe.

As limping is generally the first and most striking indication of something wrong, it may be well briefly to consider some of the causes of this symptom. For this purpose we may broadly classify limping into two categories:—

(*a*) *Painless limp.*—This may be due to shortening of the limb, paralysis, or stiffness of one joint. In all these conditions the limb is not spared as a means of support, but used to the full. The body inclines towards the affected side at every step: in shortening of one limb because one limb is shorter than its fellow; in the paralytic limp because the patient first supports himself vigorously on the affected leg, and then more firmly on the healthy leg in order to throw the diseased leg forward for the next step; and in painless stiffness of one hip because the entire extremity, including the half of the pelvis, is moved forward as a whole, the weight of the body being received by both legs equally.

(*b*) *Painful limp.*—The interdependence of all the joints of the lower extremity is very well shown when the movement of one of them becomes painful. In such a case the patient stiffens all the joints by muscular action, and avoids, as far as possible, putting any weight on the affected limb by inclining his body towards the healthy side.

Method of Examination.

In conducting an examination for conditions at or near the hip the patient should be stripped. If he is able to walk it will be easy to observe the gait and note to which category it belongs—painful or painless limp. By further inspection the experienced observer may be able, if not to make a positive diagnosis, at least to narrow down the possibilities to a very limited extent. For instance, the obliteration of the gluteal fold indicates slight flexion at the hip, which together with some muscular wasting of the thigh would indicate hip disease.

The patient should now be laid on a flat couch and directed fully to extend both lower limbs. Attention should be drawn to the comparative length of the two limbs and the curvature of the lumbar spine. If the curve be exaggerated (lordosis) *the sound limb should be flexed* as far as possible on to the abdomen—Thomas's manœuvre—for in this way the lumbar spine is flattened by rotation of the pelvis. If the affected thigh now takes up a position of slight flexion, abduction, and rotation outwards, it points to fixity of the hip-joint in this position due to muscular rigidity and most probably hip disease.

On further examination of the affected limb it will be found that the movements of the hip are restricted or abolished in every direction, all apparent movements taking place at the lumbo-sacral junction. Each movement—flexion, extension, abduction, adduction, internal and external rotation—should be tested separately and compared with those on the sound side.

Fixity of the Joint in Early Tubercle.

It is important to remember that in early hip disease a few weeks' rest in bed may cause all the symptoms to disappear; this is due to abatement of the disease brought about by the rest, and must not be thought to be due to a faulty diagnosis, as on resuming activity all the pain and rigidity reappear. The fixity of the joint in early tubercle varies in degree with whether the child is rested or tired. Abduction and rotation are the movements first interfered with. If a child is being examined after a period of rest flexion and extension may be very little restricted. In such a case a good test is to attempt to abduct the limb rapidly. Spasm of the adductors will indicate involvement of the hip-joint, even if flexion and extension are perfectly free. As the disease becomes less acute spasm becomes increasingly difficult to demonstrate, until eventually it completely disappears. Gauvain states that at the last it may be elicited in the following manner:—

> If the femur on the affected side be grasped firmly in the region of the condyles it will be found that the head of the bone may be gently rotated within the acetabulum, either inward or outward, through a varying but often considerable angle. At the point where this movement is checked a further slight sharp rotation is *instantly followed, should* the disease be still active, by spasmodic muscular contraction, not confined to muscles about the joint, but extending to the abdomen and visible in the abdominal muscles, or still more easily demonstrated if the palm of the hand is placed on the abdomen between the iliac spines. Quite a gentle and painless but sharp rotary movement is sufficient to provoke this reflex spasm of the abdominal muscles. Failure to elicit this induced spasm, Gauvain adds, "may not necessarily imply that there is no active disease, though very probably the disease is quiescent. Its presence certainly indicates an active lesion."

Direct pressure just below the mid-point of Poupart's ligament will cause pain. This is often an early sign of hip disease, and combined with muscular rigidity is pretty conclusive evidence of joint infection.

Subacute Infections Denoted by Fixity of the Joint.

Although fixity of the hip generally denotes tuberculous disease, there are other conditions which may cause a painful limp with muscular rigidity which must be excluded. Amongst these may be mentioned all forms of subacute infections of the joint. In this connexion it must be remembered that a tuberculous focus generally commences in the epiphyseal junction of the neck of the femur and must almost inevitably break through into the hip-joint owing to the anatomical relations of the epiphyseal line to the joint cavity. This sudden *breaking into the joint causes acute symptoms* with fever. A preceding history of slight articular pain would point to tubercle. A rigor or herpes labialis accompanying the acute exacerbation would be indications against tubercle.

---

[1] A paper read before the Cambridge Medical Society, Nov. 5th, 1920.

Conditions Simulating Hip-Disease.

The type of arthritis deformans sometimes met with in adolescents presents the greatest difficulty in diagnosis, as the resemblance to tuberculous disease may be very close. Even the evidence of a skiagram *may fail to be conclusive. Detection of the disease in* other joints will clear up the diagnosis.

There are other conditions, independent of the joint, which may cause pain and some restriction of movement and so simulate in some respects tuberculous disease of the hip.

Amongst these may be mentioned tuberculous disease of the sacro-iliac joint, a tuberculous focus in the great trochanter or disease of the overlying bursa, disease of the sub-psoas bursa, and psoas abscess from tuberculous disease *of the spine. In this last condition the limb is flexed and* everted; there may be lordosis, and the patient may limp in walking, but the movements at the hip are restricted only in the direction of extension and inversion, while in hip disease they are restricted or abolished in all directions. New growth in the vicinity of the hip, myeloma or sarcoma of the upper end of the femur, may simulate hip disease by causing flexion of the hip-joint and pain, leading to a painful limp. Inflamed glands in the groin, a paranephritic or appendicular abscess, may all cause spastic flexion of the hip, and an incomplete examination may lead to an erroneous diagnosis. Sciatica, neuralgia, and hysteria may all present difficulties in diagnosis and should be remembered.

Measurement.

Having conducted our examination so far, and, from the absence of pain and restricted movements in every direction, come to the conclusion that the case is not one of hip disease, we now proceed to further examination in order to ascertain the cause of the limp, excluding, for the purposes of this paper, all conditions other than those in the neighbourhood of the hip-joint.

With the limbs lying side by side, or as near the same position on either side as the condition will allow, we proceed to measure both limbs (1) from the anterior superior spine to the tip of the external malleolus, and (2) from the tip of the great trochanter to the malleolus. (In cases of extreme external rotation it may be more convenient to use the internal malleolus.) We next ascertain the relative position of the great trochanters to the pelvis. There are many ways of doing this, but the most graphic and satisfactory method is by means of Bryant's triangle. With the patient lying on his back on a flat couch, a base line is drawn from the tip of the great trochanter, prolonging the axis of the femur towards the trunk. A vertical line is drawn from the anterior superior spine to this base-line, and a third line is drawn joining the iliac spine with the tip of the trochanter. The right-angled triangle so obtained is normally an isosceles triangle. Any displacement of the trochanter upwards or backwards will alter the character of this triangle. The triangle should always be drawn on both sides for comparison, as in unilateral conditions the sound side acts as control, and even in bilateral affections the alteration in shape of the triangle is a useful diagnostic factor.

Non-traumatic Deformities Apart from Legg's Disease.

Omitting from discussion all conditions causing displacement of the trochanter which may result from injury, there are several, for the most part painless, non-traumatic deformities at the hip which have to be differentiated.

1. *Congenital dislocation of the hip.*—In this condition the head of the bone, although still within the capsule of the joint, is no longer in the acetabulum. It is generally above and posterior. The position of the great trochanter is correspondingly altered, as revealed by a long narrow Bryant's triangle with a shortened base-line. As compared with hip disease, the joint is characterised by remarkable acrobatic mobility of the thigh. The head of the femur can be moved backwards and forwards on the pelvis, and traction on the lower limb gives the characteristic "telescoping" of the leg. There is marked lordosis of the lumbar spine due to the backward implantation of the head of the femur on to the pelvis, which causes the centre of gravity of the back to fall along a line anterior to the points of body support; the backward curvature of the spine is the endeavour to bring it back again over the feet. In thin girls it is quite possible to see the head of the bone moving about, with every step, in the gluteal region. But in small fat children it is not so *evident. A general anæsthetic may even be necessary to* form a definite diagnosis. Trendelenburg's sign is characteristic of this condition. Malgaigne lays the child upon the healthy side and flexes the leg of the affected side to a right angle and slightly adducts it. One hand manipulates the limb so as to press the head of the bone as far as possible away from the pelvis. At the same time the limb is rotated. By palpation with the other hand two protuberances may be felt, one being the trochanter, the other the head of the femur. If only one protuberance is felt this is the trochanter and no dislocation is present. The history that slight lameness or waddling gait was observed as soon as the child *attempted to walk completes the evidence in favour of* congenital dislocation of the hip.

2. *Infantile paralysis.*—This condition when affecting the gluteal muscles *may sometimes cause difficulty in diagnosis.* The paralytic limp is very similar to that of congenital dislocation. The trochanter is rendered prominent by the wasting of the gluteal muscles. The undue mobility of the hip combined with some shortening of the limb completes the deception. Here, again, the history of the child having walked quite well previously, the history of an infective illness followed by widespread paralysis which gradually subsided, gives a clue as to the true nature of the condition. On examination Bryant's triangle will be unaltered, showing that the great trochanter is in its normal situation in relation to the pelvis. In progressive muscular atrophy the marked lordosis is suggestive of congenital dislocation. Examination of Bryant's triangle again prevents an error of diagnosis. If Bryant's triangle shows an abnormal position of the great trochanter without undue mobility of the hip but rather restricted movements in certain directions the abnormal position of the trochanter must be due to changes in the head or neck of the femur.

3. *Coxa vara.*—The forces acting on the neck of the femur are: (1) the downward thrust due to the weight of the body pressing on the head of the bone through the acetabulum, and (2) outward rotation of the femur, which force is brought *into play during standing and walking by the powerful* action of the glutei. This latter force is resisted by the strong ileo-femoral ligament. Any condition which causes softening of the bone will allow these forces full play and a bending of the neck of the femur results. In true coxa vara, the deformity as first described by Kocher, both these forces have acted on the neck of the femur and resulted in a bending of the neck in two planes: (*a*) a curvature with its convexity upwards due to the bodyweight thrusting down the head of the bone; and (*b*) a curvature with its convexity forwards due to the outward rotating strain acting on the neck during standing and walking. If now the head of the femur retains its normal relation to the acetabulum, the shaft of the bone, and hence the lower limb, will assume a position of marked adduction, external rotation, and hyperextension. In order to walk the limb must be brought parallel to its fellow. This is done by abduction, flexion, and internal rotation of the thigh. In extreme cases the whole range of abduction and internal rotation is taken up in order merely to attain the normal position of the limb. Hence in coxa vara these movements are restricted whilst all other movements are perfectly free. Owing to the upward lift of the trochanter there will be a corresponding shortening of the limb. The gait will be as in a case of painless limp.

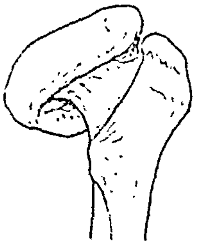
Coxa vara may be mistaken for early hip disease; like flat-foot it has a painful stage, so much so that even fixity of the joint may occur for a time. Careful examination will prevent this error in diagnosis. Coxa vara is not a disease in itself, but a deformity of the neck of the femur resulting from any condition which renders the bone unable to withstand the strains thrown upon it. Such conditions are: Early rickets, habitual carrying of heavy weights *during adolescence, adolescent arthritis deformans,* late rickets or rachitis adolescentium (which condition is for the most part confined to the ossifying junctions of the bones), and, in later life, mollities ossium, osteitis deformans, arthritis deformans, and fibrocystic disease of bone. The deformity may also result from osteomyelitis, tubercle, or fractures, or it may even be congenital.

4. *Coxa adducta.*—In this deformity the normal obtuse angle of the neck of the femur is diminished, sometimes to a right angle, and in severe cases even to an acute angle. The curvature of the neck of the femur is only in one plane, thus differing from that of coxa vara. If the head of the femur retains its normal relation to the acetabulum the

thigh would assume a position of extreme adduction, which would take up the whole range of abduction in order to attain the normal position in standing. Hence abduction is the only movement affected in this condition, again distinguishing it from coxa vara, in which both abduction and internal rotation are restricted. The conditions which produce this deformity are similar to those which lead to coxa vara. I would especially mention separation and slipping down of the epiphysis of the head, due either to trauma or late rickets.

Legg's or Perthes's Disease.

There is yet another affection of the hip to which attention should be drawn, a condition which appears to have been first described by Legg, of Boston, as early as 1909. He described it under the title "an obscure affection of the hip-joint." In 1910, Perthes, of Tübingen, apparently unaware of Legg's paper, published reports on cases of "Arthritis Deformans Juvenilis." Later on, in 1913, having excised a piece of synovial membrane, and a piece of the head of the femur from one of his cases, and finding no evidence of inflammation, he concluded that it was not an arthritis, nor did it bear much resemblance to what the Germans called arthritis deformans. But he renamed the condition "Osteochondritis Deformans Juvenilis." About the same time (1910) Calvé described a disease, which appears to be identical, and called it by the non-committal name of "pseudo-coxalgie"—a wise precaution, in that the pathology of the disease is still obscure. The condition is generally described as "Perthes's disease," although in justice to Legg's undoubted priority it should be called "Legg's disease."



Legg's disease. Specimen in the Humphry Museum. An adult femur showing flattening and curling over of head of femur like a mushroom. There is no deposit of bone upon the neck or any other part of the femur. Is this the ultimate result of Legg's disease?

This affection of the hip occurs in children between the ages of 3 and 12 years. Of 50 collected cases 40 were in boys and 10 in girls. The subjects are apparently in perfect health, strong and robust. It is not common. Delitala found only 6 cases in 1500 cases of "hip affections of orthopædic nature." In that the first symptom is a limp, with perhaps a certain amount of pain—which, however, is never severe—it may be taken for early hip disease.

Clinical examination.—There may be some prominence and elevation of the trochanter with a little shortening of the limb (½-1 in.). Bryant's triangle will show a correspondingly shortened base-line. On testing the movements, flexion and extension will be found to be perfectly free and painless. Internal rotation may be slightly limited, but abduction will be markedly restricted. The condition is almost always unilateral and the disability slight. It is distinguished from the juvenile type of arthritis deformans in that in the latter there is more pain, loss of movement, and deformity. In Legg's disease there is no crepitation on movement or other sign of involvement of the articular surfaces.

X ray examination.—By this means marked changes are observed. In a typical case the upper border of the bony nucleus of the femoral head, instead of being represented by a segment of a circle, is shown as a flat surface. In photographic prints (positives) light spots may be seen in the head which are supposed to be islets of cartilage, showing irregularity of ossification. The epiphyseal line between the head and the neck is irregular or even segmented. The neck of the femur is more pervious to X rays than its fellow and its contour may be irregular. The acetabulum may be blurred or irregular.

The characteristic feature of the disease is the astounding X ray picture associated with little or no disability.

Ætiology.

A large percentage of recorded cases give a history of injury four to six months previously. It is said to be often seen after reduction of congenital hip dislocation, occasionally on the sound side. It has been suggested that hypothyroidism is to blame, as in some cases a family history of this defect has been elicited. Gauvain, amongst others, suspects the condition to be an infection, and has reason to suppose that the infection is protozoal rather than bacterial. Roberts believes the condition to be a result of congenital syphilis in spite of a negative Wassermann reaction, arguing that subjects with frankly syphilitic bone lesions and with a definite family history of syphilis often give a negative reaction, and also that the pathological findings in Perthes's disease coincide with osteochondritis, one of the most common expressions of bone syphilis in children. Finally, he points out that the course of Perthes's disease is similar to that of many other syphilitic joint conditions in that the destructive process is self-limited and that there is a tendency to more or less complete restoration of function. Whether or no some constitutional condition underlies Legg's disease has not yet been proved. It is certain, however, that the disease must be one of three pathological processes—namely, new growth, inflammation, or degeneration—due to some circulatory disturbance. There is nothing to suggest new growth. As regards inflammation, Ely rightly states that it is not likely that a destructive inflammation could exist in the head of the femur without causing symptoms or an arthritis. No evidence of an arthritis has been adduced. As regards degeneration due to some circulatory disturbance, there are certain points worthy of consideration.

Traumatic Injury.

First, although trauma has been discounted as a causative factor, it should be noted that a large proportion of recorded cases give a definite history of injury some few months previous to the onset of symptoms; secondly, that the disease occurs more frequently in boys, who are proverbially more prone to injury, than in girls, in the proportion of 4 to 1; and thirdly, that the disease has only been observed in the epiphyseal head of the femur, the epiphysis most subjected to strains and contusions. As no theory of infection or constitutional condition can alone explain why Legg's disease only occurs at the hip, let us assume that trauma is a definite causative factor.

Circulatory Disturbance.

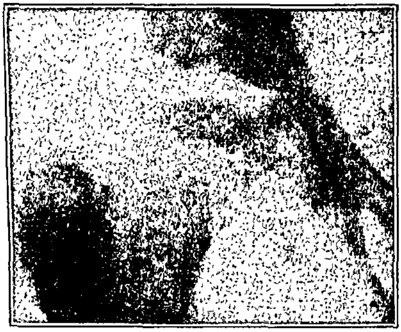
In the absence of positive evidence of inflammation let us also assume that the disease is of the nature of degeneration due to some circulatory disturbance. In support of this assumption there are certain anatomical points of interest in connexion with the upper epiphysis of the femur which may have an important bearing on the incidence of Legg's disease at this epiphysis to the exclusion of all other epiphyses.

With the exception of the head of the radius, the epiphysis of the head of the femur is the only epiphysis whose surface is entirely covered with articular cartilage. Except for a few insignificant vessels which enter the head through the site of the ligamentum teres, the epiphysis is entirely dependent for its blood-supply on the small vessels entering the circumference where the epiphysis joins the neck, thus differing from the lower epiphysis of the femur, for instance, which has large areas covered with periosteum on the mesial and lateral condyles, from which it derives a free supply of blood. True, Kolliker has observed blood-vessels burrowing into the epiphyseal cartilage from the diaphysis, but this supply would be small. The nutrition of cartilage has not been fully worked out yet. Strangeways asserts that articular cartilage is nourished by the synovial fluid, and that the changes found in osteo-arthritis are secondary to defects in the secretion of the synovial membrane. At birth the upper epiphysis of the femur includes the great trochanter, thus resembling at this age the upper epiphysis of the humerus. The neck of the bone is developed as an upward extension of the shaft, which eventually divides the epiphysis into two, one portion forming the head and the other portion the trochanter. This division is completed about the third year, the earliest age at which Legg's disease has been observed. From this age onwards the restricted blood-supply of the head would obtain.

Skiagraphic Evidence.

Any injury causing a separation, or partial separation, of this epiphysis, or severe contusion of the epiphyseal junction might seriously interfere with the blood-supply, which disturbance might lead to degeneration of the cartilaginous head. Skiagraphic evidence would seem to support this theory.

The flattening of the head by the pressure of acetabulum due to the weight of the body suggests a softening of the cartilage forming the head. The irregularities in ossification evidenced by the transparent islets suggest rather circulatory disturbance than infection. And, lastly, the apparent displacement of the epiphysis, often described, is suggestive of trauma. The changes in the acetabulum may very well be secondary to those in the head. The disease, resulting as it does in so little disability and tending to more or less complete restoration of function, the opportunity of obtaining specimens during the active period of the disease, must, of necessity, be rare. Our evidence is, therefore, almost entirely skiagraphic, and until the interpretation of bone lesions, as shown by X ray, is based on a wider experience of comparison of skiagrams of specimens of known conditions with those found in the living, so long will the pathology of many bone diseases remain obscure. There is a wide field for research in this direction. The affection runs its course in two to three years. Its most active period is one year. Even after all symptoms have subsided and a cure evidently has been obtained, the X ray may still show an alarming picture.



Skiagram of Legg's disease of right hip.

Treatment.

As regards treatment, most surgeons seem to have considered that none was called for. Fixing the thigh in an abducted position by means of a plaster-of-Paris splint and allowing the child up on crutches with a patten under the sound foot until the more acute stage has passed would seem the most rational procedure to adopt.

Before concluding I will briefly describe one of my cases, that of a boy, aged 13, but markedly underdeveloped, an only child of healthy parents, with no history of important previous illness.

In January, 1917, he began to limp and complained of shooting pains in left leg, which symptoms increased so that in March, 1917, he was unable to walk; the mother stated he had marked muscular wasting of thigh. He was taken to a hospital where his left leg was put into a Thomas's splint and kept therein for 1 year 4 months, being removed in August, 1918. The boy was necessarily lame for a time, but gradually improved, until in a few weeks he did not limp at all. In October, 1919, he began to limp again with little or no pain, and *in March, 1920, came* to my out-patient's department complaining of limp and pain in right knee, hip, and back. I obtained a history of his having fallen off a baker's cart six to seven years before with no apparent injury. On examination I found over ¾ inch shortening on right side, free movements of flexion and extension, but restricted abduction. Bryant's triangle showed a shortened base line. The X ray picture revealed a condition similar to that described as occurring in Legg's disease. Wassermann reaction was negative.

Summary and Conclusion.

It will be seen that affections at the hip fall into two groups: (1) those in which there is pain and muscular rigidity, restricting movement of the joint in every direction, the most common and important member of this group being tuberculous disease of the hip; (2) those in which there is little or no pain and no muscular rigidity, but rather undue mobility or restricted movements in certain directions only. Under this group fall congenital dislocation of the hip, coxa vara, coxa adducta, and Legg's or Perthes's disease. After a careful and methodical physical examination has been made and an opinion formed as to the nature of the case the patient should be referred to the radiologist for skiagraphic evidence, not, as is so often done, for diagnosis. X ray diagnosis unsupported by clinical evidence is sure, sooner or later, to lead to serious error. The surgeon and the radiologist should work together. This is but another example of the value of "team-work." It is essential that both joints should be photographed. In order to minimise errors of reading which may result from differences in exposure, developing, or the position of the plates in relation to the bones, both hips should be taken on the same plate. The sound joint is our only reliable control. In cases of early hip disease the changes may be so slight that without the sound side to compare with it is almost impossible to be certain as to the normal outline of the bone, or as to whether there is narrowing of the shaft due to atrophy, abnormal transparency of the bone (osteoporosis), or whether the gap, representing the articular cartilages on the head of the femur and acetabulum is of normal thickness, or whether small foci of disease exist.

I must not, however, trespass on the province of the radiologist. I will content myself by re-emphasising my remarks as to the necessity of surgeon and radiologist working together. The clinical picture and the skiagram are often diametrically opposed. In tubercle, for instance, physical examination, on the one hand, finds a subject with pain and fixed hip-joint with consequent grave disability. The X ray, on the other hand, especially in cases of primary synovial infection, may show nothing at all, whereas in Legg's disease the radiologist may be staggered by the alarming picture presented by the skiagram, whilst the surgeon finds a patient with little or no disability. Team-work is the keynote of future medicine and surgery. It is thus, and thus only, that the best results will be obtained.

THE FREQUENCY OF LATENT SYPHILIS IN A MEDICAL DEPARTMENT.

BY TH. E. HESS THAYSEN, M.D.,
PHYSICIAN TO "DE GAMLES BY," COPENHAGEN.

THE great value of the Wassermann test in a medical clinic is a well-known fact, established by numerous investigations both in the New World and in the Old. The question of the frequency of latent syphilis[1] among patients in a medical department has not, however, yet been settled, because as a rule a W. test has been carried out only where the clinical symptoms point to syphilis or where there has at least been cause for suspicion thereof. For the discovery of latent syphilis it is necessary also to perform a W.R. in those cases where neither the history of the case nor the clinical examinations give any reason for considering the patient as a syphilitic, as only in this way are we able to discover the cases where the positive W.R. is the only sign of the luetic infection. Such researches have been made by *Fildes in 1917, Bruhn in 1916, Weill in 1914*, in Denmark by Scheel and Arne Faber in 1917, and by Meulengracht in 1919. Interesting investigations have been performed by Fildes on out-patients at the London Hospital, who did not suffer from any medical disease, while Bruhn examined patients, amongst whom were several soldiers, at the dermatological clinic in Charlottenburg, near Berlin. The results gained by these authors can therefore not be compared with others derived from a medical department. In his treatise, which I only know from a short account in *La Presse Médicale* Weill does not state in how many cases he found latent syphilis.

Between April 1st, 1917, and April 1st, 1918, I have performed the W. test on 738 patients at St. Johanesstiftelsen. All patients over 15 years of age admitted there were examined except those who died at once or a few hours after their admittance; a few were omitted accidentally, but the essential fact is that no selection has taken place among the patients. All the W. tests were performed at the State Serum Institute of Copenhagen with the technique described by Boas in 1910. The cases in the tables have been divided into two groups, in the first of which are collected those patients who gave a positive history of primary infection, and in the second those in whom the case-history was negative in this respect. In each group it has been estimated how many patients could be recognised as syphilitics by clinical examination alone, judging from typical symptoms.[2] I admit that the limits of what we can recognise clinically as syphilis have been rather strictly defined, but for practical reasons I have omitted a group of "probable syphilitics."

---

[1] The name latent syphilis was invented by Fournier, for cases only recognised in the tertiary stage. Since the introduction of the W. test we must add those cases in which the positive W.R. is the only sign of the luetic infection.

TABLE I.—*Cases with History of Syphilis.*

Sex.	W.R.	Clinical symptoms.	Total number.	Sex.	W.R.	Clinical symptoms.	Total number.
Men	+	−	15	Women	+	−	8
		+	5			+	4
	−	−	9		−	−	6
		+	7			+	4

TABLE II.—*Cases without History of Syphilis.*

Sex.	W.R.	Clinical symptoms.	Total number.	Sex.	W.R.	Clinical symptoms.	Total number.
Men	+	−	12	Women	+	−	24
		+	5			+	10
	−	−	283		−	−	335
		+	5			+	6

A comparison between Tables I. and II. shows us, that out of 32 patients in Table I. with positive W.R., clinical symptoms were found in 9 cases; and out of 51 in Table II. in 15 cases. All patients in the first table had had previous treatment, but none in Table II. In 655 patients with negative W.R. clinical symptoms of syphilis were found in 22 cases; in half of them there was no evidence of previous infection. In 83 patients with positive W.R. clinical symptoms were found in 24 cases. In 36 of these 83 patients the positive Wassermann was the only sign of possible syphilis, or what led to a decision to consider them as syphilitics.

It is among these 36 patients and 11 cases with negative W.R. and clinical symptoms of syphilis, that we may expect to find the cases of latent syphilis.

The Diagnostic Value of the Wassermann Test.

How many of the former 36 patients we can regard as syphilitics depends upon the value one can ascribe to the W. test as an aid to diagnosis. The point of view which demands that the smallest dose of serum (0·2 c.cm.) must inhibit hæmolysis completely if the reaction is to be regarded as specific, will certainly be justifiable when the rare non-syphilitic diseases giving positive W.R. can be excluded. This standpoint is maintained by Craig, and agrees with the experiences gained in this country. Table III. shows that complete inhibition was found *in 30 patients by* employing 0·2 c.cm. serum; in 18 of the 19 in which the test was repeated the reaction was again positive, and only became negative at a third examination after treatment (Nos. 13, 17, 28). In one case, No. 9, the reaction was negative at a second examination, although the patient had not been treated. This case must be excluded as doubtful. The remaining 29 cases can with fair probability be regarded as syphilitic. In Case 15 a partial inhibition was found at two examinations at about a fortnight's interval; this patient can with fair probability be considered as a syphilitic. In the remaining five cases partial inhibition was followed by a negative reaction. Thus, among 36 cases there are 30 (20 women and 10 men) which we look upon as most probably syphilitics. (Table III.)

These patients have been examined with special care in order to find signs of syphilis. The history of the cases have been taken in as much detail as possible.

As already mentioned, it is difficult to see in Weill's treatise in how many cases the positive W.R. was the only sign of existing syphilis. Arne Faber, who examined 1233 patients, found 29 positive W.R. without any other sign of syphilis, and all the patients denied previous infection. In 21 of these (13 women and 8 men) complete inhibition was found by employing 0·2 c.cm. serum. Arne Faber does not state in how many cases the reaction was repeated, only that this was done. Meulengracht found, among 504 patients, 10 in whom the positive W.R. was the only sign of syphilis, while quite confident in considering the patients as syphilitics.

The Statistics Examined.

I can throw no light on the great differences in the frequency of latent syphilis found by these workers owing to the deficient history obtainable in the cases in my series. This was only to be expected, as the greater part of my patients are old; Faber in accordance with Meulengracht found that barely half (45 per cent.) of his syphilitic patients gave evidence of previous specific infection. Among 114 syphilitics I found 52 only who gave a clear history of a primary sore.

A glance at the class of patients in the departments which furnished material for this examination gives us, on the other hand, some explanation. Faber performed his investigations at the municipal Bispebjerg Hospital, which admits patients mainly of the middle classes of Copenhagen. Meulengracht investigated the medical clinic of the University, at which the greater number of patients come from the country population. My patients are taken from a hospital which only admits the poorest, of whom no doubt many have been infected at a time when neither the knowledge of syphilis was as widespread as it is now nor the diagnosis as certain. Finally, we must allow for some difference in the interpretation of what clinically can be recognised as syphilis and what not, especially between Faber's and my patients. It seems that Faber means that a pure aortic insufficiency is a sign of syphilis, whereas I, in accordance with the post-mortem examinations of Flojstrup, only do so if the history of the case shows evidence of syphilis or other signs of this disease. Flojstrup found that in 22 cases of pure aortic insufficiency only 13 suffered from syphilis. From Faber's treatise it is impossible to see to how great a degree our notions of what can be recognised as syphilis differ, so that I am unable to interpret his figures quite. His investigations are, however, still the easiest to compare with mine. Doing so we find:—

Faber	1233 patients,	with	21 cases,	1·7	per cent.
Thaysen... ...	738	„	„ 30 „	4·1	„
In all	1971	„	„ 51 „	2·6	„

The approximate frequency of ignored latent syphilis discovered only through the W.R. among patients in a medical department which admits patients of all ages, above 15 years, from a large town is, as we see, about 2·5 per cent. of the whole number.

In Table IV. I have collected syphilitic patients according to their age in groups of 5 years from 20 to 80 years of age. In the cases where I have been able to ascertain at what age the patients in my series have contracted the syphilitic infection it has varied between the ages of 18 to 40, the average age being 26. If we reckon the age of 25 as an average we find the following based on Faber's and my series of cases: 8 patients have had the syphilitic infection for 15 years, 19 from 15 to 30 years, 12 from 30 to 45, 10 from 45 to 60 years, without it having given any symptoms which clinical examination could detect.

TABLE IV.

Age.	No.	Age.	No.	Age.	No.
21-25	2	46-50	4	66-70	2
26-30	2	51-55		71-75	1
31-35	4	56-60		76-80	1
36-40	2	61-65		80	1
41-45	9				

Looking through the diseases for which these patients were admitted, we find nothing characteristic. The cerebro-spinal fluid has been examined in six of my patients; 5 showed negative W.R., whilst one, No. 4, was positive; *this patient was being treated for chronic nephritis and optic atrophy.* The amount of cells in the cerebro-spinal fluid was not increased in the 5 cases examined. A post-mortem examination has taken place on 5 of my patients mentioned here without it having been possible to discover any macroscopic sign of syphilitic disease. Of the 5 cases, one had a syphilitic liver, and in another the post mortem was only partial. In all the other cases all organs, the brain included, have been examined.

The other group of latent syphilis contains 11 patients in whom the W.R. was negative, but where clinical symptoms made it most probable that they had been suffering from syphilis (Table V.). The cases are collected in Table V.; as far as we know, none of the patients had ever been under antisyphilitic treatment. As we see by the table, Argyll Robertson's phenomenon was in four cases the only sign of syphilis. It is well known that this phenomenon is frequently an additional finding in syphilitic patients treated for other diseases; Faber's researches distinctly show this circumstance. Thus the whole group of latent syphilis comprises 41 cases in 738 patients, or 5·6 of them all, 36 per cent. of the syphilitic. Among these we find 30, or 4 per cent., of the whole group where the W.R. is the only sign of the specific infection. Even if this figure is too high, being rather about 2·5 per cent. or less, it is high enough to demand our full attention, and it raises the following two questions, already put forward by Scheel.

Problems Arising.

Firstly, is it necessary to perform a Wassermann on all patients admitted to a medical department?

This question must be answered in the affirmative when the patients are from a large city. The gain is not only that in some doubtful cases the exact therapeutic method which alone can bring about the cure is applied, but also, as Scheel strongly emphasises, the patient undergoes a special examination in order to discover signs of an active process, if possible. There is in these cases special reason to emphasise the great importance of such a thorough examination of the central nervous system as cannot be carried out on all patients admitted to a medical department. Often enough it has been pointed out that one naturally cannot conclude that the disease is due to syphilis because the W.R. is positive, and the frequency of these cases alone shows how much caution is demanded in this respect.

Secondly, should all these cases be treated? This is not as easy to answer as it might seem, because it is often of vital importance to the patient from a social point of view not to be treated as syphilitic. Even if it is usually possible in a hospital to adopt therapeutic methods without awakening suspicion in those around the patient, this is not always possible in daily life, and a look at Table IV. shows that the syphilitic virus in these cases has been a particularly inactive one, in spite of the great strength of the W.R. in several of them (Table III.). It seems to me that the only way to decide this difficult question lies in a consideration of the ages of the patients. Even if a careful clinical examination of all organs can detect no symptoms of syphilis whatever the patient must be treated as thoroughly as possible if he is less than 50 years of age,

TABLE V.

No.	Age.	Sex.	Clinical symptoms of syphilis.
1	64	Man.	Saddle-nose.
2	73	„	Argyll Robertson pupil.
3	57	„	„ „ „
4	72	„	„ „ „
5	69	„	Aortic aneurysm.
6	86	Woman.	Cicatrices palati duri et mollis.
7	78	„	„ „ „ „
8	66	„	Tabes dorsalis.
9	74	„	„ „
10	64	„	Argyll Robertson pupil.
11	41	„	Saddle-nose.

while I should prefer to wait for clinical symptoms if he is older. An essential thing in these cases is that the patient's private doctor is informed.

The generally accepted opinion that a positive W.R. means that the syphilitic infection is still active is based, so far as I can see, mainly upon the following two observations: (1) that the W.R. generally becomes negative during the treatment that cures the manifest syphilitic symptoms; (2) that a formerly negative W.R. can be changed into a positive one, when the old disease breaks out again or new symptoms occur.

From the first observation no other conclusion may be drawn at the moment than that the positive W.R. is influenced by the treatment; it does not justify the assumption that because the W.R. has become negative the patient's syphilitic infection has been cured. The second observation will have no value in this connexion until it has been proved that the change from a negative into a positive reaction is almost always followed by clinical symptoms, or that these arise much more frequently in the presence of a positive than of a negative W.R. We are, so far as I know, still waiting for the answer to these questions—an answer which only can be given by examinations made on a great number of syphilitic patients through several years, watching for new syphilitic symptoms or changes in those already existing and comparing them with the results of the Wassermann test.

When among 114 cases of syphilis we are able to discover no less than 30 in whom the syphilitic infection can only be discovered by the examination of the blood, in spite of the fact that the infection in many of the cases dates from several years back, this striking observation throws a different light on the prognostic value of the positive W.R. than that mentioned above, and the question arises, Where in the body are the substances formed which produce the positive W.R.? To the five post-mortem examinations mentioned above I am able to add two more. One of the patients (No. 7 in Table III.) died later; a careful examination of all organs, including the brain, could detect no syphilitic changes whatever. In the case of another patient, a woman, 72 years of age, who had been a prostitute for several years and had contracted syphilis when 20 years old, I could detect only an Argyll Robertson pupil as a clinical sign of syphilis; cerebro-spinal fluid was normal in all respects; the blood showed a positive W.R. (0-60-100) on three separate occasions. She died from carcinoma of the stomach; at the post-mortem examination I could not find any sign of a syphilitic change in the brain or any other organ. A careful microscopical examination of brain, liver, aorta, kidneys, adrenals, pancreas, and spleen showed only senile changes and a slight chronic nephritis due to arterio-sclerosis.

It is difficult to bring these findings into accordance with the generally accepted opinion that the positive W.R. indicates a still active syphilis, and that the antibodies that produce the W.R. are formed in the organs where the syphilitic inflammation has taken root. Does the positive W.R. in these cases indicate that somewhere in the body, perhaps in the bone marrow, there still is a depôt of spirochætes from where the antibodies come, or does the positive W.R. mean that the syphilitic infection is dead, while the antibodies are still present in the blood? If the first supposition is right we find an analogy in the Widal reaction, which sometimes persists for years in patients treated for typhoid fever; if the second comes nearer to the truth, the analogy lies in the Pirquet reaction in tuberculosis, which is still present even if the specific lesions are calcified.

THE ACTION OF QUININE ON PREGNANT UTERUS.

BY HUGH W. ACTON, M.R.C.S., L.R.C.P. LOND.,
MAJOR, I.M.S.

(From the Department of Pharmacology and Biochemistry, National Institute for Medical Research, Hampstead.)

THE physician in the tropics is frequently called upon to treat an attack of malarial fever in a pregnant patient, and is invariably asked his opinion on the effect that quinine will have in precipitating labour. Our knowledge on the action of this alkaloid on pregnant uterus has, up till now, been based mainly on clinical experiences. We know that quinine can induce labour, yet if given as an ecbolic agent it often as not completely fails. H. P. Dimmock (1893) considered, as the result of a large practical experience gained at Bombay, that quinine in the ordinary therapeutic doses of 5 to 10 gr., three times a day, could be given with safety during pregnancy. W. C. Swayne and E. Russell (1919) discussed in 1919 the trial of a herbalist who was tried before the Recorder at Bristol on a charge of procuring an abortion by quinine. The Recorder, in his summary, asked the jury to decide whether quinine was a noxious drug: (1) in ordinary doses, (2) in large doses. The jury replied to (1) No; to (2) Yes, and these answers express the popular and current opinion held on the ecbolic action of quinine. J. E. Atkinson (1890) in an able summary of the clinical evidence considered that the ecbolic action of quinine was largely due to an idiosyncrasy of the patient. His conclusions were as follows:—

(1) The cinchona alkaloids have not a fixed and definite influence in causing contractions of the uterus.

(2) An oxytocic action is occasionally produced by these remedies. Their action depends on idiosyncrasy, as in the other idiosyncratic reactions to cinchona, it is impossible to tell in any given subject its manifestations.

(3) There is some evidence that the action is only excited under large doses, and in debilitated subjects.

(4) Cinchona and its derivatives should be employed during pregnancy with great circumspection, and should be at once withheld upon the supervention of symptoms indicating a uterine motor influence.

The majority of the writers on this subject have failed to consider a very important additional factor that occurs during the course of a malarial attack—viz., death of the fœtus from the effects of high temperature. The action of quinine in controlling the malarial fever, and so preventing inter-uterine death of the fœtus, far outweighs any effect this drug may have in precipitating labour. The ecbolic effect, as I will now proceed to show, only occurs under certain conditions.

Technique.

The test animal was killed, and the uterus was excised as rapidly as possible and placed in a bath of Ringer's solution containing traces of magnesium chloride at 37° C. After opening the abdomen an incision was made through the centre of the vagina, the cut vaginal end was lifted up with forceps, and the broad ligament divided throughout its length so as to free the left horn of the uterus and ovary on this side. The right horn of the uterus was divided from the left by cutting through the upper end of the cervix. The left horn and its fœtal contents (moderately advanced in gestation) were removed to the bath. The vaginal end was fixed to a glass tube bearing a platinum needle, and the ovarian end by a platinum needle which was attached by a hair to a writing lever. The recording of the contractions was done on the drum by a glass frontal writer, described by Lovatt Evans (1919). The bath was kept at a constant temperature of 37° C., and a continuous supply of oxygen was maintained by means of a fine spray of this gas delivered from the bottom of the glass holder fixing the vaginal end. Except in one experiment the lever at the writing end was counterbalanced by a heavy weight. The bath, apparatus, &c., was of a general type described by H. H. Dale and Laidlaw.

The standard base solution was prepared as follows:—

One g. of anhydrous base was dissolved in 27 c.cm. N/HCl to form the soluble bihydrochloride, and about 120 c.cm. of distilled water were added to make the volume up to 150 c.cm.; 27 c.cm. of N/NaOH were slowly added, constantly shaking in order exactly to neutralise the whole of the hydrochloric acid. The volume was then made up with distilled water to exactly 200 c.cm. in a measuring flask. The standard solution was a 1-2000 solution of anhydrous base in normal saline—i.e., 1 c.cm. contained 0·5 mg. of anhydrous base. The requisite amount of NaCl was formed by the action of the HCl and NaOH. This solution was warmed over a water-bath and added to the uterine bath in the required doses. Quinine and the other cinchona alkaloids can only circulate in the blood in the form of a base, which acts as an alkali; for this reason the base was chosen instead of acid salts.

The Effect of Quinine Base on the Pregnant Uterus.

In a paper read before the Therapeutic Section of the Royal Society of Medicine I pointed out that the dextrorotatory cinchona alkaloids—i.e., cinchonine and quinidine—had a greater action than the lævorotatory isomerides—i.e., cinchonidine and quinine—in increasing the amplitude and rhythm of uterine contractions in non-pregnant guinea-pigs. This finding probably holds good for pregnant muscle as well, but I should have required much more material conclusively to prove the point, as the variations in response to different stimuli are considerable when one is testing pregnant uterus. As the object in this research was to explain the action of quinine on the pregnant uterus, my tests were mainly carried out with this alkaloid. One can safely say with regard to the action of these cinchona alkaloids, that whatever effect quinine has on pregnant uterus, the others will only differ from each other in degree of action.

TEST 1.—*Guinea-pig's uterus.*—4 mg. of quinine base was allowed five minutes' contact and was then thoroughly washed away with three changes of Ringer's solution at 37° C. The capacity of the bath was 175 c.cm., this corresponds roughly to a concentration of 1-44,000. After the uterus has settled down to its normal rhythmic contractions 4 mg. of quinidine base was next allowed five minutes' contact. After washing the uterus free from quinidine cinchonine was tested, but owing to the insolubility of the base the same dose of alkaloid was tested, dissolved as a hydrochloride. All three alkaloids caused a marked increase of tonus in concentrations of 1-44,000. As a result the uterus is contracted rigidly round the fœtus. The membranes remained intact in spite of the contractions, as the rigidly contracted os gave sufficient support to prevent their rupture.

TEST 2.—*Rat's uterus.*—Guggenheim (1912) showed that histamine, which caused a marked contraction of the uterine muscle in all other species of animals, when tested on rat's uterus caused relaxation instead of contraction. In this test the pregnant uterus of a white rat was used, and the four alkaloids quinine, hydroquinine, quinidine, and hydroquinidine were tested alternately. The alkaloids were made up as a 1 per cent. solution of anhydrous base dissolved in the requisite amount of N/HCl to form bihydrochlorides. 2 mg. of each alkaloid were placed in a 150 c.cm. bath for five minutes, and then thoroughly washed away with Ringer's solution. The uterus was allowed to settle down to the rhythmic contraction of the excised pregnant uterus. This test shows that quinidine and hydroquinidine are slightly stronger in their action on rat's uterus than quinine and hydroquinine. With none of the four alkaloids is the amplitude of the normal rhythm increased; the rhythm is accelerated and the relaxation diminished, so that the main effect is some increase of tonus. There was no dilatation of the os uteri.

Effects of Different Concentrations of Quinine Base on the Pregnant Uterus.

In a recent paper King and the present writer showed that when a single dose of quinine was taken on an empty stomach by one of us, the concentration of quinine in 5 c.cm. of blood varied with the size of the dose ingested, thus:—

(*a*) After 1 g. of anhydrous quinine base dissolved as bisulphates (approximately 20 gr. of sulphate). The concentrations found in the blood were: at the first hour, 1-150,000; second hour, 1-187,000; third hour, 1-225,000.

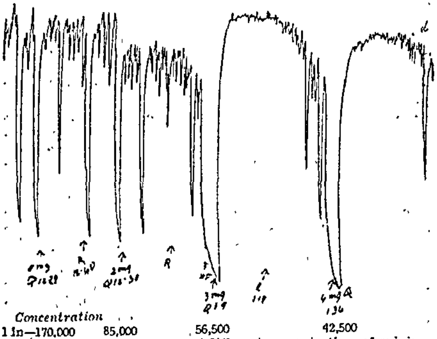
(*b*) After 0·5 g. of anhydrous quinine base (approximately 10 gr. of sulphate): at the first hour, 1-250,000; second hour, 1-280,000.

(*c*) After 0·25 g. of anhydrous quinine base (approximately 5 gr. of sulphate): at the first hour, 1-378,000; second hour, 1-750,000.

These results indicated the necessity of testing the effect of different concentrations of quinine on the pregnant uterus.

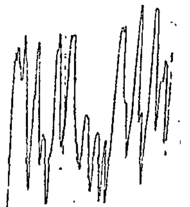
TEST 3.—*Guinea-pig's uterus.*—In this test increasing doses of anhydrous quinine base commencing with 0·5 mg. were added at intervals of two minutes without washing out; the amount was gradually increased until a total of 4 mg. had accumulated in the 150 c.cm. bath. This concentration of 1-37,500 produced a state of persistent tonus previously described, and to show its sustained character it was recorded for 30 minutes. This test shows that with a 0·5 mg. dose—i.e., 1-300,000 concentration, there was no effect seen. With 1 mg.—i.e., at 1-150,000, the amplitude was increased and somewhat sustained. It was not until a concentration of 1-37,500 was attained that the uterus was maintained for a space of 30 minutes in a state of high tonus.

TEST 4.—*Guinea-pig's uterus.*—In this test the whole dose—i.e., 1, 2, or 4 mg.—was put into the bath. After each test the uterus was well washed with Ringer's solution and allowed to relax before the next dose was tested.



GRAPH 1.—Showing the effect of different concentrations of quinine base on pregnant guinea-pig's uterus. (The mark R indicates the washing out with Ringer's solution.)

1 and 2 mg. of quinine base in a 170 c.cm. bath—i.e., a concentration of 1 in 170,000 and 1 in 85,000 respectively—produced little effect on the contractions of this pregnant uterus. The 3 and 4 mg. doses (1-56,500 and 1-42,500) produced a tonus effect. On this uterus a small hole was now cut over the fœtal sac, and a 4 mg. dose was again given. The contraction induced by this dose of quinine forced the membranes through the rent and they ruptured. It was difficult to see what was happening through this depth of Ringer's fluid. After rupture of the membranes one saw that the hole was too small to allow the fœtus through. Washing with Ringer's solution caused relaxation of the tonus, which was renewed on adding a further dose of 2 mg., producing a concentration of 1-85,000.



GRAPH 2.—Showing the effect of 1 mg. (1-170,000) of quinine base on the pregnant uterus of a guinea-pig which was accidentally wounded. After the quinine was introduced definite labour pains set in and the fœtus was driven through the accidental tear in the uterus. (The time record indicates intervals of 10 seconds.)

Action of Quinine on the Uterine Muscle.

We know that during labour the longitudinal muscles of the upper uterine segment act as the driving force in expelling the fœtus from the uterus; synchronously with this contraction the circular muscles of the lower uterine segment relax to allow the head to pass through this narrow segment of the uterus. In all these experiments with quinine on the pregnant uterus, one saw that the contractions equally affected both the longitudinal and circular fibres. In spite of the violent contractions produced by stimulation of the longitudinal fibres, the os remained tightly closed, so that the fœtus still remained in the uterus. On one occasion when a hole was made through the uterine wall the membranes ruptured, but the fœtus was still retained.

TEST 5.—*The left horn of the uterus, in being cut away from the right horn, was accidentally incised by the point of the scissors.* This was not noticed at the time and the uterus was placed in the bath for testing. In this experiment the weight on the lever was small. 1 mg. of quinine was placed in the 170 c.cm. bath, marked Q 1 in the graph. A violent contraction of the uterus occurred and labour pains set in, and the whole of the uterine contents were driven through this artificial hole in the side of the uterus. The record is shown in Graph 2.

Summary of the Experiments.

The action of quinine in certain concentrations causes contraction of both the longitudinal and circular fibres of the uterus. The effect produced depends on the concentration of quinine present—weak concentrations 1–300,000 have no effect; concentrations of 1–150,000 produce contractions under certain conditions, whilst a concentration of 1–44,000 produces a tonic spasm, which, if sustained, would cause asphyxia of the fœtus from constriction of the placental sinuses. This concentration could only be attained if the patient was nearly poisoned by a large dose of quinine. The degree of concentration in the blood varies with the dose taken and on individual susceptibility depending on the rate of absorption. Cinchonism is correlated with the concentration of quinine present in the blood and varies with different individuals, and is more frequently seen with weak and anæmic persons. Concentrations of 1–150,000, such as occur with large doses, increase the strength of the intermittent uterine contractions, and if some exciting cause was present—e.g., weak membranes or a patulous or dilated os—the pressure produced by the increased contractions might be sufficient to cause rupture of the membranes or dilatation of the os, and so bring on labour.

Therapeutic Recommendations.

1. The controlling of the fever by quinine or other cinchona alkaloids must be the first objective in the treatment of these cases. We know that high temperatures soon cause death of the fœtus, and this factor is sufficient to induce premature labour. The mother's temperature should be carefully watched and prevented from exceeding 103° F. by sponging, &c.

2. The avoidance of large doses of these alkaloids. As soon as the diagnosis of malaria is made, which is an urgent matter in pregnancy, quinine or quinidine should be given at once as the case requires. It is better to divide the doses into 2½ or 5 gr. doses given every two or four hours. 20 gr. a day is sufficient, and ample to control any attack of malarial fever.

3. The employment of general methods for the prevention of miscarriage—viz., complete rest in bed and the judicious use of opium in allaying any mental excitement. When the child is dead or the miscarriage inevitable quinine should be given in ordinary doses and the case treated on general obstetrical lines.

I must finally express my gratitude to Dr. H. H. Dale, F.R.S., for permitting me to work in his laboratory, and for the help and advice he gave me during the course of these experiments.

ROYAL UNITED HOSPITAL, BATH.—At the close of 1920 there was an adverse balance of £15,000 against this hospital. The National Relief Fund has granted the institution £12,500 from the £700,000 set apart to help out the war deficits of voluntary hospitals.

AN UNUSUAL FATAL CASE OF INFECTION WITH B. ENTERITIDIS OF GAERTNER.

BY J. W. MCNEE, M.D., D.SC. GLASG., M.R.C.P. LOND.,
MEDICAL UNIT, UNIVERSITY COLLEGE HOSPITAL.

IN a recent issue of THE LANCET, A. B. Rosher and G. Selby Wilson[1] describe a case having many similarities to enteric fever, but due in all probability to infection with the *Bacillus enteritidis* of Gaertner. Their report has recalled an unusual fatal case of infection with the same organism, seen by me during the war, which amplifies many of their findings. The notes of the case are briefly as follows:—

Pte. J., aged 25 years, became ill on Nov. 20th, 1917, with shivering and pains in the head and limbs. High fever was present, without pulmonary or intestinal symptoms, and a provisional diagnosis of trench fever was made. Eight days later the patient suddenly had a "fit," and bit his tongue during the convulsion. Next day he appeared better and was transferred from the field ambulance to a corps rest station. Almost immediately another convulsion took place, and he was sent on to a casualty clearing station, where he was first seen by the writer. After admission, 12 convulsions occurred within a few hours, and he became semi-comatose. A specimen of urine was obtained, but contained only a trace of albumin. On the suspicion that the case might be cerebro-spinal meningitis, lumbar puncture was carried out on Dec. 2nd, but the fluid was quite clear and contained no excess of cells. Signs of pulmonary involvement now developed, and within three days the base of each lung was found to be consolidated. A specimen of urine, examined on the 7th, was decidedly smoky, and contained red blood corpuscles and a large amount of albumin. He died during the afternoon of the 7th, 17 days after the onset of his illness. From Nov. 29th, until death occurred, he remained in a semi-comatose state. Vomiting occurred frequently during the illness, but there was never diarrhœa at any time.

Since the man was in various hospitals no complete temperature chart is available. He is known, however, to have had high fever for over a week after the onset of the illness. On admission to the casualty clearing station the temperature was subnormal, and remained so until three days before death, when it rose to 102° F. at the time when signs of pulmonary involvement became manifest.

Post-mortem.

A post-mortem examination was made 16 hours after death. There was no œdema of the face or limbs. Herpes was present on the lower lip. On removing the calvarium very striking œdema of the cerebral meninges was found. In section the brain substance showed many "puncta cruenta," but no actual hæmorrhages. An excess of fluid was present in each lateral ventricle. The pericardial sac was normal and the heart healthy. The air-passages, from the pharynx down, were removed intact along with the lungs. The trachea was seen to be half-filled with yellowish pus, often in the form of small, worm-like masses. The mucous membrane, when the pus was removed, was found intensely congested and ulcerated in places.

The lungs were voluminous, and showed many petechial hæmorrhages beneath the pleuræ. The upper halves of each organ were somewhat emphysematous, and the finer bronchi in this situation did not contain any pus. The lower parts of each lung were irregularly consolidated, some areas being much firmer than others. In section the appearance was extraordinary. Each small bronchiole stood out as a bright lemon-yellow spot from which, on pressure, a small worm-like purulent cast could be squeezed out. Each of the bronchioles was surrounded by a wide zone of hæmorrhage, forming a ring about the size of a shilling. Further away from the bronchioles the general appearance of the lung tissue was an almost uniform deep purple colour. The results of examination of the pus from the bronchi will be referred to later on.

The peritoneum was normal, and on careful examination of the stomach and intestines no trace of ulceration or of any inflammatory change was found anywhere. The fæcal material in the colon was of normal type, and contained neither mucus nor blood. The liver was somewhat fatty, but not otherwise unhealthy. The spleen was distinctly enlarged, and the pulp very soft. The kidneys presented many changes of interest. Both were large, and weighed together 402 g. They were very firm to the touch, and the capsules were tensely stretched. The capsules were definitely adherent, but could be removed with a little difficulty so as to cause only small tears of the cortical tissue. In section the cortex was of a deep purple colour, and the normal markings were obliterated. The medulla also shared in the intense congestion. The whole appearance corresponded to an acute hæmorrhagic nephritis, and this was confirmed by histological examination.

---

[1] A. B. Rosher and G. Selby Wilson: A Case of Enteric Fever due to the *B. enteritidis* of Gaertner, THE LANCET, Jan. 1st, 1921, p. 16.

One eyeball was removed for examination. A condition of early "choke-disc" was found, but there were neither white spots nor hæmorrhages in the retina.

Since this case occurred at a time when influenzal broncho-pneumonia was just beginning to be prevalent, associated at times with nephritis, a diagnosis of influenza at once suggested itself in this case also. At the autopsy, moreover, the macroscopic lesions in the lungs appeared typical of influenzal broncho-pneumonia. A film of the bronchial pus, stained by Gram's method, showed the presence of numerous small Gram-negative bacilli, which at first sight seemed entirely confirmatory of the influenza hypothesis. The organism appeared to be present in almost pure culture. Later, an examination of films from the spleen-pulp showed an abundance of similar small bacilli. Careful cultivations were made on plates of agar, smeared with rabbit's blood, as was in use at the time in the laboratory for the cultivation of Pfeiffer's bacillus. After 24 hours an abundant growth was obtained on all the plates, both from the bronchial pus and from the spleen-pulp. The colonies were, however, larger and more opaque than those of Pfeiffer's bacillus on the same medium, and their abundance caused doubts to arise of their nature. Subcultures were therefore made on ordinary agar and in peptone broth, with the result that the organism was found to be a motile bacillus, with a growth on agar resembling one of the typhoid-coli group. On testing the sugar reactions of the bacillus, glucose, mannite, and dulcite were fermented with the production of acid and gas, while lactose remained unchanged. Litmus milk was made acid, but was not coagulated. An agglutination test was thereupon carried out, using paratyphoid A and paratyphoid B antisera. Agglutination resulted with the paratyphoid B serum, but was only complete up to one-quarter of the full titre of the serum. The test with antiparatyphoid A serum was quite negative. A subculture was sent to the Lister Institute, and a report from there stated the organism to be a true *B. enteritidis* of Gaertner, the differentiation being confirmed by the requisite absorption tests.

Discussion and Summary.

The case described by Rosher and Wilson affords an instructive comparison with my own. My patient was only seen late in the illness, at first during an apyrexial period, and no suspicion of infection with an organism of the typhoid group ever entered my mind. Their case was observed from the outset, and the symptoms were such as to suggest a possible diagnosis of enteric fever. Their case fortunately recovered, and their diagnosis was made by agglutination reactions only. In my case the diagnosis was made by the more absolute method of isolating the organism in abundance from two situations after death. In both cases a suspicion of influenzal infection arose, dependent on the presence of broncho-pneumonic signs in the chest during life in one case and at autopsy in the other. It seems possible, from analogy with my own case, that the causal organism might have been isolated from the sputum in the other case also.

The chief points of interest which emerge from a consideration of the two cases appear to be: 1. Anomalous cases of infection with the *B. enteritidis* of Gaertner can occur, without any of the acute diarrhœal symptoms commonly associated with the "food-poisoning" group of organisms. 2. The possibility of obtaining the causal organism from the sputum in cases of infection with organisms of the typhoid and food-poisoning groups, accompanied by bronchitis, should not be forgotten. During the war I have on various occasions readily isolated either *B. typhosus* or *B. paratyphosus B* from the sputum in these infections where bronchitis (quite apart from actual broncho-pneumonia) existed. Bronchitis accompanied by expectoration is such a well-known complication of these fevers that this occasional added source of examination for the organism should not be lost sight of in cases where the ordinary routes (blood, fæces, and urine) fail. The isolation of a known pathogenic organism must always make the diagnosis more satisfactory than agglutination tests alone, and this is, of course, especially true where inoculated individuals are under investigation.

A SIMPLE PROCEDURE FOR THE

ACCURATE ENUMERATION OF BLOOD CELLS AND BACTERIA

WITHOUT THE USE OF A COUNTING CHAMBER.

BY GEORGES DREYER, C.B.E., M.A., M.D.,
FELLOW OF LINCOLN COLLEGE; PROFESSOR OF PATHOLOGY
IN THE UNIVERSITY OF OXFORD.

(From the Department of Pathology, University of Oxford.)

Wright was the first to elaborate a method for determining the number of bacteria per unit volume of a given suspension without the use of a counting chamber. His method[1] consists in mixing equal volumes of human blood and the suspension to be counted, and preparing films from the mixture. The films are dried, fixed in perchloride of mercury, suitably stained, and the relative number of human red cells and of bacteria present in each field are counted. Taking the number of red cells per cubic millimetre of human blood to be 5,000,000, the actual number of microbes per unit volume is readily calculated. The introduction of this technique marked a great advance along the lines of simplicity and speed. However, it is apparent that the accuracy of the final results is dependent upon the knowledge of the exact number of red cells per cubic millimetre of the blood employed. We know, indeed, that not only does the number of red cells per unit volume of blood vary considerably in different persons, but also that the number of cells varies definitely in the same individual at different hours of the day. For this reason Wright's method does not claim to yield more than approximately accurate results, unless the number of human red cells in the blood employed be enumerated each time by careful counting in an accurate chamber. Futhermore, the less skilful technician may experience some difficulty in making films which give a fairly even distribution of microbes and red cells, owing to their difference in size. It is evident, also, that the method cannot be employed for counting human red cells, as there is no means of differentiating between the standard cells and the red cells to be counted.

The procedure hereunder described, although based upon the same general principles as Wright's method—namely, the easily recognisable differences between the cells to be counted and those taken as a standard, differs in that it can be used to count not only bacteria but also human blood cells, and that the standard consists of a permanent suspension containing an exactly determined number of corpuscular elements per unit volume.

The corpuscular elements selected for the preparation of the standard emulsion are the red corpuscles of the blood of a hen. The fowl should be young and in good health. The reasons for the selection of the red cells of the hen are the following:—

1. The cells are of uniform size.
2. They are of approximately the same specific gravity as mammalian red cells.
3. The cells are slightly larger than the human red cell or average mammalian red cell.
4. They are readily distinguished from mammalian red cells by their elliptical shape and the presence of nuclei,

---

[1] Wright, A. E.: Technique of the Teat and Capillary Glass Tube. London: Constable and Co. 1912.

which make it impossible to confuse them with mammalian red cells in a mixture of the two.

Preparation of the Standard Suspension.

Prepare a solution containing approximately 1·3 per cent. perchloride of mercury in sterile normal (0·85 per cent.) saline solution. Bleed the fowl directly into this solution, allowing approximately 1 c.cm. of blood to each 100 c.cm. of the solution. Agitate the recipient fluid gently while the blood is being added, so as to ensure a thorough mixture. Leave for one hour, shaking from time to time to prevent sedimentation of the blood. At the end of the hour centrifugalise *just enough* to deposit the red cells, pour off the supernatant fluid, and fill up to the original volume with a solution of 4 per cent. perchloride of mercury in normal saline solution. Allow the mixture to stand for six hours, occasionally shaking the flask or bottle. At the end of this time agitate the flask to emulsify the cells and then centrifugalise. Wash the cells twice with normal saline solution, each time emulsifying them before centrifugalising. Pour off the supernatant fluid, and fill up to the original volume with normal saline solution to which has been added a minute amount of perchloride of mercury—i.e., just enough to prevent bacterial infection.

The suspension is now ready for standardisation. As the result of a large number of experiments, I have arrived at the conclusion that a convenient suspension to work with is one which contains about 20,000 cells per cubic millimetre. Therefore, the suspension should be brought to this standard in the usual manner, using normal saline solution as the diluting fluid, and counting at least 1000 cells in each of 10 successive drops, or about 10,000 cells in all.

Standard suspensions thus made have been kept for eight months at ordinary temperatures without showing any change in the number or appearance of the corpuscles.

Determination of the Number of Red Cells in a Given Blood by Means of the Standard Suspension.

The blood, taken in the usual manner, is diluted 1 : 200, with a solution of 1·3 per cent. perchloride of mercury in normal saline solution. For example, one adds 0·1 c.cm. of the blood to 19·9 c.cm. of the mercury saline solution, previously measured into a test-tube, carefully washing out the blood pipette and thoroughly mixing the resulting dilution. The tube containing the blood dilution is shaken to secure an even distribution of the cells in the suspension and immediately 1 volume—e.g., 0·1 c.cm.—of the fluid is transferred to a dwarf test-tube. In the same manner the tube or bottle of standard suspension is shaken and an equal volume of this fluid is measured into the dwarf test-tube, which is agitated so as to mix the fluids thoroughly. A drop of the mixture is placed immediately upon a clean slide and covered with a coverslip, care being taken to avoid air bubbles. The drop should be only large enough to form a thin film between the coverslip and the slide, and not so large that the coverslip floats. A coverslip of convenient size is 22 mm. × 22 mm.

For counting, a magnification of about 350 is convenient; for example—one can use a Zeiss D achromatic objective, and a Zeiss No. 3 Huyghenian eye-piece. Into the eye-piece place a small diaphragm of black paper, in the centre of which is an aperture 4 mm. × 4 mm., which gives a field of convenient size. In counting one should avoid the extreme periphery of the area covered by the coverslip. The number of nucleated red cells and the number of non-nucleated cells in each field are enumerated. It is advisable to count two drops from the same mixture, and not less than 500 cells in each drop.

Calculation of the Number of Red Cells Contained in Each Cubic Millimetre of the Blood Examined.

Take the sum of all the nucleated cells counted, and the sum of all the non-nucleated cells. Divide the number of nucleated cells into the number of non-nucleated cells. Multiply this factor by the number of cells in each cubic millimetre of the standard suspension (20,000) and then by the dilution of the blood (200). The product is the number of red cells per cubic millimetre of the blood examined. It is clear that the method can equally well be applied to the counts of nucleated erythrocytes. In such a case the standard suspension must be made with non-nucleated red cells.

Example.—Suppose the standard suspension contains 21,000 nucleated red cells per cubic millimetre. The blood sample is diluted 1 in 200. A drop of a mixture of equal volumes of these two solutions is prepared for the microscope and about 50 fields are counted. The sum of the nucleated red cells in the 50 fields is 319; the sum of the human red cells in the 50 fields is 405.

$$\frac{405}{319} \times 21{,}000 \times 200 = 5{,}294{,}000.$$

Therefore the blood examined contains 5,294,000 red cells per cubic millimetre.

Leucocytic Count.

To determine the number of leucocytes in a given blood sample by this method the procedure is as follows:—

Into a dwarf test-tube measure 3 volumes of a 0·3 per cent. solution of acetic acid in distilled water, to which has been added 0·6 per cent. of a 1 per cent. solution of methyl-violet (6 B). Add 1 volume of the blood to be examined, mix carefully, and allow to stand for a short time until the human red cells are hæmolysed. Then add 1 volume of the standard suspension of nucleated red cells and mix carefully. Place a drop of the mixture on a clean slide and cover with a coverslip, observing the same precautions as in the case of the red-cell count previously described. For counting use the same objective and ocular as for the counting of red cells, but the paper diaphragm previously used in the ocular should be left out, and the nucleated red cells and leucocytes present in the whole field should be counted. The same total number of cells—i.e., about 500—should be counted as in the case of the red-cell determination.

The calculation of the number of leucocytes per cubic millimetre of blood is performed in the manner already indicated above—namely, by dividing the number of nucleated red cells into the number of the leucocytes, and multiplying this factor by the number of cells in 1 c.mm. of the standard suspension. If dilutions other than those here indicated are used the calculation will naturally have to be modified accordingly.

Example.—Suppose the standard emulsion contains 21,000 nucleated red cells per cubic millimetre. One volume of the blood to be examined is added to 3 volumes of the acetic-acid-methyl-violet solution, and mixed. To this mixture is added 1 volume of the standard suspension. Seventy fields are counted, giving a total number of 409 nucleated red cells and 145 leucocytes.

$$\frac{145}{409} \times 21{,}000 = 7445.$$

Therefore the blood examined contains 7445 leucocytes per cubic millimetre.

Enumeration of Bacteria.

For counting bacteria in a suspension the following technique has been adopted:—

A special standard suspension for this purpose is prepared as follows: The perchloride-fixed nucleated cells are washed several times with normal saline solution to remove the free perchloride, and then made up with sterile normal saline solution to a standard of about 30,000 per cubic millimetre. To secure sterility a minute amount of formalin is added. For the purpose of counting a mixture of 1 volume of the standard suspension, 1 volume of the bacterial suspension suitably diluted, and 1 volume of 0·5 per cent. methylene-blue solution is prepared and counted, as in the case of the blood count, enumerating the nucleated cells and the bacteria in each field.

Example.—Suppose the standard suspension contains 30,000 cells. The bacterial suspension is diluted 1 in 200. Into a dwarf test-tube is measured: 1 volume of the standard suspension, 1 volume of the diluted bacterial suspension, 1 volume of 0·5 per cent. methylene-blue solution, and the test-tube shaken to thoroughly mix the contents. A drop of this mixture is immediately transferred to a slide, covered with a coverslip, and counted as in the case of the white-cell count, except that an oil immersion lens is used. Eighty fields are counted, giving a total number of 500 nucleated red cells and 400 bacteria.

$$\frac{400}{500} \times 30{,}000 \times 200 = 4{,}800{,}000.$$

Therefore the bacterial emulsion contains 4,800,000 bacteria per cubic millimetre.

To compare the relative merits of this method with those of the counting chamber extensive series of comparative counts have been made. The accurate Bürker chamber made by Zeiss was used. As an illustration the following example may be given:—

To eliminate errors of sampling all of the test suspensions were prepared from a single sample of blood, made up with normal saline solution to a dilution of 1 : 100. Into each of five test-tubes was measured 5 c.cm. of this suspension, care being taken to secure an even distribution of the blood cells. To the tubes marked A, B, C, D, and E were then added respectively 6 c.cm., 3 c.cm., 7 c.cm., 5 c.cm., and 4 c.cm. of the mercury perchloride normal saline solution previously mentioned, giving final dilutions of the blood as follows:—

A, 1 : 220; B, 1 : 160; C, 1 : 240; D, 1 : 200; and E, 1 : 180.

The extent of dilution of the samples in the different tubes was unknown to me until after the actual counting of the cells was finished. At least two separate drops of each dilution were counted, both in the case of the differential method and in that of the Bürker counting chamber. The details of the experiment are given in the following table:—

Test-tube.	Final dilution of same original sample of human red cells.	No. of human red cells per c.mm. (Average count of *two* drops.)	
		Differential method.	Bürker counting chamber.
A	1/220	5,509,000	5,456,000
B	1/160	5,366,000	5,326,500
C	1/240	5,419,000	5,270,500
D	1/200	5,238,750	5,387,000
E	1/180	5,401,000	5,546,000
	Average ...	5,386,750	5,397,200

In the case of the differential method, an average of 360 nucleated cells and an average of 550 human red cells were counted in each drop, making a total of 910 cells per drop. In the case of the counting chamber method, on an average 1030 cells per drop were counted. The average count for the two drops of the same suspension was in both cases taken as the figure representing the number of human red cells per cubic millimetre. Obviously, if it were possible to eliminate all errors of dilution, distribution, and enumeration, the final figures arrived at for each of the five dilutions would be identical. In an actual experiment, however, identical results are not attained, and for this reason the average of the five is in both cases taken as the figure representing the actual number of red cells per cubic millimetre of the blood examined.

The close correspondence between the results obtained by the two methods is striking. By the differential method it is found that the blood examined contains 5,386,750 red cells per cubic millimetre, while by means of the Bürker chamber it is found to contain 5,397,200 red cells, which gives a difference between the results obtained by the two methods of 10,450—i.e., 0·19 per cent. If we examine the percentage deviation of each count from the average this is found to be 1·25 per cent. in the case of the differential method, while it is 1·46 per cent. in the case of the counting chamber method, although in the latter case a larger number of cells is counted. Furthermore, if we calculate the percentage deviation for the figures obtained from the counting of each individual drop by both methods, it is found to be 2·29 per cent. by the differential method and 2·46 per cent. by the counting chamber method.

Conclusions.

By careful procedure, and by counting the numbers of cells indicated above, it is evident that the method discussed in this paper yields extremely accurate results, which compare more than favourably with the results obtained by the use of a counting chamber. It furthermore possesses the following distinct advantages: (1) It can be used with equal facility for counting erythrocytes, leucocytes, and bacteria; (2) it does away with the use of a costly counting chamber; (3) it is quicker and less fatiguing to the eye.

CENTRAL MIDWIVES BOARD FOR SCOTLAND.—At a meeting of the Board held in Edinburgh, Sir J. Halliday Croom in the chair, the Viscountess Novar took her seat as a member of the Board. Sir Halliday Croom, in a valedictory address on his retirement from the Board, thanked the members for the loyal support he had received as Chairman, and referred to the pleasant and harmonious way in which the work had been carried out. On the motion of Dr. A. Campbell Munro, seconded by Sir Archibald Buchan-Hepburn, a hearty vote of thanks was accorded to Sir Halliday Croom for the efficient manner in which he had discharged the duties as Chairman of the Board since its formation five years ago. The Board also expressed its appreciation of the able and valuable services rendered by Mr. D. L. Eadie, the secretary. It was intimated that the new Board would be constituted early next month.

FURTHER RESEARCHES UPON
ANTIMONY IN THE TREATMENT OF FILARIASIS.

BY GEORGE C. LOW, M.A. ST. AND., M.D., C.M. EDIN., M.R.C.P. LOND.,
SENIOR PHYSICIAN, HOSPITAL FOR TROPICAL DISEASES, LECTURER AND CONSULTING PATHOLOGIST TO THE LONDON SCHOOL OF TROPICAL MEDICINE;
AND
ELIZABETH J. O'DRISCOLL, M.B. N.U.I., D.P.H. D.T.M.,
HOUSE PHYSICIAN, HOSPITAL FOR TROPICAL DISEASES.

IN THE LANCET of Sept. 11th, 1920, one of us (G.C.L.), in conjunction with Dr. A. L. Gregg, published the details of a case of *Filaria bancrofti* infection treated by intravenous injections of antimonium tartaratum (tartar emetic). In this individual case no beneficial results were obtained, the infection persisting, even though 17½ gr. of the drug in all had been administered. We pointed out in that paper the great importance of doing prolonged examinations—both before, during, and after treatment—of measured quantities of blood, and indicated that that was the only way one could determine the efficacy or otherwise of the drug used. Since that time we have had the opportunity of studying two further cases of *Filaria bancrofti* infection; one in minute detail, the other not quite so fully, but still sufficiently so to draw conclusions as to the efficacy of antimony as a drug in the treatment of filariasis. The details of the two cases are as follows:—

CASE 1.—History: A. H., 30, an Indian native, was born and lived in Calcutta till he went to sea as a ship's steward at the age of 18. In this capacity he visited many parts of the world—East Africa, Bombay, &c.

Previous illnesses: No malaria; has had dysentery; no history of syphilis.

Present illness: For the last few years has been complaining of indefinite pains in the region of the stomach and liver; these at times have been acute, and vomiting has been associated with them. Lately the pain has been radiating to the right shoulder, and has been specially severe at nights. He came to hospital—to out-patients—to see if anything could be done for it. Admitted into hospital, his stools were found to contain *E. histolytica* cysts, and his night blood many filarial embryos. Examination: Heart and lungs normal. Urine: No albumin, blood, or sugar. Abdomen: Liver not enlarged; slight tenderness on deep pressure; no evidence of gall-stones or duodenal ulcer; spleen not enlarged; colon, no thickening.

Blood: R., 3,840,000; W., 5,200; Hb, 80 per cent. Night blood, many embryos of *F. bancrofti* present; 40 in 20 cubic millimetres of blood.

Fæces: *E. histolytica* cysts present.

Filarial condition: No evidence of any clinical signs of the infection present.

As the case presented such a good filarial infection, as evidenced by the embryos in the blood, it was resolved to do a very careful and accurate analysis of these before, during, and after treatment with antimonium tartaratum. Table I. gives these details. A study of this table brings out several important facts, and not the least interesting of these is the almost complete disappearance of the embryos from the blood when no treatment was being given between Oct. 20th and 26th. Why this took place is not clear, but it illustrates, if that is necessary, the importance of many examinations in such cases, and also the danger of concluding that a disappearance of embryos is necessarily associated with any individual drug one happens to be giving at the time. It is well known, of course, that when a severe attack of lymphangitis appears the embryos may disappear at once from the peripheral blood and not return again, but this explanation will not apply here, as there was no lymphangitis and the embryos reappeared in numbers again. After the ratio became more or less constant the injections of antimony were begun, and a glance at the table at once shows, just as in the case reported before,[1] that the drug had no effect whatsoever on the number of embryos circulating in the blood—that is, was not affecting the adult worms producing them.

Incidentally another drug, emetine, was tried at the same time as the antimony, this being given for the

s done was as follows. The patient came into
ital about 4 P.M., had his injection, stayed in the
t—so allowing of his midnight blood being taken— and then went out to his work next morning. Table II. gives the result of the blood counts (measured quantities) and the dosage of antimony employed.

It will thus be seen that in this case also there was no beneficial effect from the antimony injections, and after the careful study of these two cases it is difficult to see how the drug can be of any use at all in such infections.

It is, however, by the intravenous route, that we must hope for future success, and we are now considering the possibility of trying other drugs in a similar manner. The arsenical group also appears to be useless, so unless some of the other metals prove efficacious little remains to be done and the treatment of filariasis will remain in its present unsatisfactory condition. Emetine, as we have shown in Case 1, also had no effect upon the infection.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF ACUTE ASCENDING PARALYSIS

OCCURRING AS A COMPLICATION OF MEASLES AND TERMINATING IN RECOVERY.

BY C. R. BOX, M.D., B.SC. LOND., F.R.C.P.

THE following case seems worthy of record on account of its rarity. The cord inflammation present was evidently either toxæmic or infective in character, ascending in type, and, from the dissociated character of the accompanying anæsthesia, presumably situate in the central grey matter. The case was under the care of Dr. R. W. Rix, of Sudbury, who made the notes.

A girl of 14 was taken ill on April 20th, 1920, and was kept in bed. On the 24th measles declared itself. The temperature was 103° F., the rash of average intensity, and the child was not more ill than is usual with measles. Two days later the temperature had fallen to 99°, and the patient appeared well on the way to recovery, but next day the temperature rose again to 103°, although no pulmonary complication could be detected.

During the night the child attempted to get out of bed and found that she could not stand. After this she had a constant desire to micturate but could not pass water properly, a few drops only coming away at each attempt. The next day when examined there was paralysis of all the muscles of both legs except the hamstrings and the flexors and extensors of the great toes; these muscles were extremely weak. The muscles of the abdominal wall were acting, although feebly. Tactile sensation seemed intact, but loss of appreciation of heat and cold came to light in a curious manner; the abdomen was painlessly burned by a hot-water bottle during an attempt to stimulate the bladder. The knee-jerks and abdominal reflexes were absent. The bladder was obviously distended and overflow incontinence occurred on coughing. The temperature was 102° and moist sounds were audible in the lungs. Later in the evening 20 ounces of urine were withdrawn by catheter, and the administration of urotropine in 10 gr. doses every four hours was commenced. The next day the recti abdominis were paralysed and the cough ineffective, although the intercostals were still working. The legs were quite helpless.

On the 30th—six days after the appearance of the measles rash and the fourth day of paralysis—I saw the patient. With the *exception of very slight power of extension of the left foot the legs* were completely paralysed; so also were the recti abdominis. The intercostals appeared weak and cough was ineffective. The patient also complained of slight loss of power in the left arm, which she discovered on attempting to use a small nail-file. Up to the level of the sixth dorsal segment appreciation of pain and of heat or cold was absent, although tactile sensation appeared to be intact. Sense of position was present; there was no limiting zone of hyperæsthesia. No definite loss of power and no defect of sensation could be found in the arms. The ocular fundi were quite healthy and there was no cranial nerve paralysis. The right knee-jerk was absent, the left very sluggish. The abdominal reflexes were in abeyance. During the period from the 27th to the 30th the temperature varied between 101° and 102.°

On May 1st there was evidence of commencing recovery, the cough becoming much stronger and the temperature lower. The next day the temperature became normal and voluntary movement of the toes appeared, followed later by movements of the ankles. From this time improvement was continuous. Recovery took place in the following order: Rotators of hip-joint and sensation of slight discomfort when pricked on the 4th. Abduction and adduction of both thighs with slight power of extension of knees, flexion of right knee and return of left knee-jerk on the 5th. On the same day the patient for the first time complained of the discomfort of the burn on the abdomen and the sense of heat and cold returned to the front of both legs. All movements of the legs were present on the 6th, and heat and cold sense had returned everywhere. On this day the patient passed water naturally for the first time since April 28th

The abdominal muscles contracted voluntarily two days later and the feet could be lifted off the bed. The knee-jerks returned and the plantar reflexes, the latter being doubtfully extensor. By June 8th the patient walked well with the exception of slight foot-drop on the left side. The knee-jerks gradually became exaggerated and the plantar response was extensor in type. For some time the bladder remained irritable, possibly on account of the urotropine. It was discontinued on the 13th. During the whole period of paralysis the patient was aware when the bowel was going to act, but at first could not control it; after May 29th, however, control was gradually re-established.

At the time of sending this report, seven months after the commencement of her illness, the only evidences of what the patient passed through are visible exaggeration of the tendon-jerks in legs and arms, absence of the superficial abdominal reflexes, and a very doubtful extensor response in one foot. Over a small area of skin at the back of the left knee she experiences a sensation of what she terms numbness where there is slight impairment of appreciation of heat and pain. Micturition is at times somewhat imperative and her legs easily become tired.

Reference to similar cases will be found in Sir Dawson Williams's article on measles in Sir Clifford Allbutt's "System of Medicine," and recovery appears to be the rule rather than the exception. Sir Thomas Barlow has recorded a case in which disseminated myelitis was found in a case of measles which proved fatal.

Devonshire-place, W.

PERCENTAGE AND FRACTIONAL DILUTIONS.

BY WILLIAM FLETCHER, M.D. CANTAB.,

BACTERIOLOGIST, INSTITUTE FOR MEDICAL RESEARCH, KUALA LUMPUR, FEDERATED MALAY STATES.

MY excuse for writing this note, which may appear puerile and unnecessary to those who have had a mathematical training, is that most medical men have but little knowledge of figures, and I have seen them toiling, with knitted brows and well-sucked pencils, in their efforts to discover how to prepare, for instance, a 33 per cent. from a 50 per cent. solution; while well-known text-books devote several pages to tables for the purpose of making higher from lower dilutions.

The average civilised man can count two quite easily; for instance, he knows how to prepare a 40 per cent. solution from one of 80 per cent. by taking one part of the latter and making it up to two parts by adding an equal quantity of the diluent. This is the same thing as taking 40 parts and adding sufficient diluent to make 80. What is not generally realised is that all other dilutions can be *prepared on the* same principle; for example, a 30 per cent. solution can be made from one of 50 per cent. strength, by taking 30 parts of the latter and making it up to 50; or a 40¼ per cent. solution can be prepared from one of 79½ per cent. by taking 40·25 c.cm. of the latter and adding sufficient diluent to make 79·5 c.cm. That is to say, an x per cent. solution can be prepared from a y per cent. solution by taking x c.cm. of the latter and diluting it sufficiently to make y c.cm.

The preparation of other fractional dilutions is equally simple. As everyone knows, a 1 in 10 (written 1/10) solution can be made from a 1 in 5 (1/5) solution by taking 5 parts of the latter and diluting it up to 10 parts, but it is not generally known that all dilutions can be prepared in the same way; that, for instance, a 1/97 dilution can be made from a 1/8 dilution by taking 8 parts of the latter and making it up to 97. In short, a $1/x$ solution can be prepared from a $1/y$ solution by taking y c.cm. of the latter and adding sufficient diluent to produce x c.cm.

By this method the medical man can not only calculate quickly but do it "in his head."

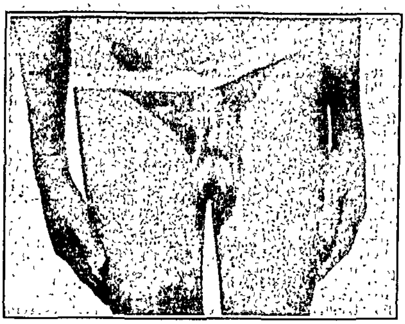
A TRI-ORCHID.

BY V. R. SUNDARESA AYYER,

CAPTAIN, I.M.S.; COMMANDING NO. 15 SANITARY SECTION, KARACHI.

THE following note may be of interest, since I can find no record of a similar case in the medical literature at my disposal.

The patient, R., was an enrolled follower, aged 19, a native of the Trichinopoly District, in South India. He arrived at the Followers' Central Depôt, Kirkee, in August, 1918, and was medically examined when about to proceed in a draft for overseas service in October, 1913. A third testis was found above the left normal one, with a separate globus major and minor and a separate cord, distinctly traceable alongside the normal left cord up to the left internal abdominal ring. It was moored to the left wall of the left sac of the scrotum above the normal left testis. The component parts of the third cord were easily felt, and the "testicular feel" on pressure over this gland was the same in every way as that over the other two normal glands.



The after-history of the patient is not recorded, as his present whereabouts cannot be traced.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

CLINICAL SECTION.

EXHIBITION OF CLINICAL CASES.

A MEETING of this section of the Royal Society of Medicine was held on Jan. 14th, Sir ANTHONY BOWLBY, the President, being in the chair.

Several interesting cases were shown, among which the following were included.

After-results of Ligature of Left Subclavian Artery for Aneurysm.

Mr. W. G. SPENCER showed a patient in whom the first part of the left subclavian artery was ligatured for aneurysm in 1899. When admitted to hospital at the age of 43 there was an aneurysm of the second and third part of the left subclavian artery the size of a duck's egg. He had had syphilis 14 years previously, and three years before admission he had been in a hospital for ten months suffering from (? syphilitic) bronchitis with profuse hæmoptysis, which was, however, diagnosed as incurable phthisis. He had a gumma on the left leg and another on the left thigh. In April, 1899, the first part of the left subclavian artery was ligatured, but pulsation in the aneurysm recurred and in the following June the vertebral and inferior thyroid arteries were tied by reopening the previous wound upwards, and the third part of the subclavian was tied through the axilla. The patient had now been readmitted complaining of pain along the course of the sixth to ninth left intercostal nerves. He was now 65, and he had a markedly emphysematous, rigid chest. There was no sign of the former aneurysm except the scars. A skiagram of the chest and also auscultation had failed to find positive evidence of a thoracic aneurysm.

The PRESIDENT remarked upon the successful issue of the operation, and said that the usual happening after ligature of the larger vessels for aneurysm was the subsequent development of intrathoracic aneurysm beyond the reach of further operative treatment.—Dr. F. PARKES WEBER said that he was interested in the fact that this patient must have had syphilitic disease of the lung at a time when its existence was denied.

Mr. SPENCER also showed a case of

Epithelioma Supervening in the Scar

eight years after the destruction of a hairy mole by X rays. The patient was a woman, aged 28, who had had a hairy mole on the left temple. Monthly exposures to X rays had been continued for two years. After the final exposure the scar had remained sound until three months ago. There was now an epitheliomatous ulcer at the outer angle of the left eye infiltrating the eyelids. Keratosis was present in patches over the scar area. He spoke of the danger of a treatment which left a burn-like scar for a condition not in itself serious, and which could be removed by incision.

Dr. J. A. BIRRELL showed a case of

Extreme Dislocation of the Heart into the Right Axilla.

The patient, a man aged 39, was passed fit for military service in 1915. Previous to that he had worked for 17 years in a pill factory and had apparently been free from any disease. In the winter of 1915-16 he developed a cough but was kept on duty, and in the following summer he collapsed from shortness of breath whilst "doubling" with a gas mask on. After another medical examination he was at once returned to duty. In 1917 he received a shrapnel wound in the right calf and popliteal region, but did not remember being struck on the chest. The wound was treated surgically under a general anæsthetic a few days later, and shortly after he developed fever which lasted three weeks, and he said that he wore a "pneumonia jacket." The temperature subsiding, he was transferred to England, where in 1918 he was told that his heart was beating in the wrong side of his chest, and he began to notice a sensation of thumping in the same position after exertion. He was discharged unfit for further service on account of gunshot wound and pulmonary tuberculosis. He now had a cough, the expectoration was yellowish-green, and repeated examinations failed to show the presence of tubercle bacilli or of elastic tissue. Pneumococci, streptococci, and micrococci catarrhalis were present, the temperature and pulse were normal, and he was short of breath on exertion.

On physical examination the heart was found to be dislocated so far to the right that the impulse could be felt in the fifth intercostal space in the right axillary line. Percussion showed corresponding dislocation to the right, so that the left border of the heart was in the fifth right space, three inches from the middle line of the body. There were no murmurs, but the aortic second sound was very accentuated and was best heard in the dome of the axilla. On X ray examination the heart was seen to lie close against the outer wall of the right chest, and the diaphragm was one inch higher than normal. The outlines of the aorta could not be defined. The trachea could be seen at the right border of the sternum, and when the patient swallowed barium sulphate the shadow could be followed down the right border of the vertebral column until it crossed the spine to reach the stomach.

Clinical examination showed that there was considerable contraction of the right lung. The whole of the right side of the chest was dull to percussion and very dull from the level of the sixth dorsal spine to the lower costal margin. Cavernous breathing and whispering pectoriloquy were audible in the right interscapular and infraspinous areas, and at the inferior scapular angle râles were occasionally to be heard, especially after a cough. There was no clubbing of the fingers, the dorsal spine was concave to the right, and the trachea was seen to be dislocated to the right of the middle line. No foreign body could be demonstrated in the air passages. There were signs in the right lung indicative of collapse of the right lower lobe. The Wassermann test of the blood was negative.

The case was shown: (1) because of the extreme dislocation of the heart: (2) because of the difficulty in explaining the condition of the right lung, which did not appear to be due to bronchiectasis or to tuberculosis, but was suggestive of the pleurogenous pneumonia of Sir Andrew Clark. Were it not a fact that the patient had had a history suggesting pulmonary disorder *before* the shrapnel wound an explanation could be found for the state of the right lung: that its present condition was the result of (*a*) pneumonia developing at the time of the shrapnel wound of the leg or just subsequently; (*b*) that it was the result of massive collapse of the lung—though there was no evidence to support the view that massive collapse of the lung could persist and lead to such disorganisation of the right lung as was shown in this case.

Dr. F. S. LANGMEAD suggested that the case was one of congenital dextrocardia, and that further displacement to the right side had been caused by fibrosis of the lung following pneumonia.—Dr. WEBER also said that dextrocardia was the probable explanation, and agreed with Dr. Birrell that displacement of the heart had occurred as the result of collapse of the lung at the time of the injury and pleurogenic pneumonia.

Dr. V. WILKINSON showed a case of

Mycotic Aneurysm of the Right Calf.

The patient, aged 37, formerly a pianoforte-maker and now a discharged soldier, was recently admitted to hospital because a few weeks previously he developed severe pain and swelling of the right calf. These symptoms abated somewhat, and it was then discovered that the swollen calf pulsated. In the past he had suffered from "rheumatic pains" up to the age of 14 years, and four years ago he contracted syphilis. He entered the army in 1916 and was discharged with valvular disease of the heart in February, 1919. Since leaving the army he had become shorter of breath, had begun to sweat rather profusely at night, and pain had developed over the heart. He was first admitted to hospital in June, 1920, when double mitral disease was found; the spleen was enlarged, the fingers were clubbed, there was occasional evening temperature, and the Wassermann test was found to be positive. The heart was not enlarged. He was readmitted to hospital early in the present month. He said that 14 weeks previously he noticed pain in the right leg just above the ankle on the inner side. Fomentations gave relief and nothing further was noticed until four weeks ago, when the calf of the right leg became swollen and painful.

At the present time the right calf was obviously enlarged, was tender to the touch, and pulsated. The pulsation ceased and the swelling diminished in size when the right femoral artery was compressed. The heart was now found to be enlarged to the right and to the left, and a loud, early diastolic murmur indicating aortic regurgitation had developed since he was admitted to hospital last year. In addition to the other signs then found the patient had begun to look ill, there were blood and albumin in the urine, and a constant rise of temperature, loss of weight, and progressive secondary anæmia, the leucocytic count now amounting to 6000 per c.cm.

The case was shown as a rather unusual example of mycotic aneurysm occurring in malignant endocarditis.

The PRESIDENT said that aneurysms due to septic infarction were of two kinds. In the first blood was extravasated into the soft tissues from a hole in the vessel at the site of the embolus and thus produced a false aneurysm, and in the other a true aneurysm was produced by dilatation of the vessel itself. He thought that this was a case of false aneurysm. It had to be remembered that septic embolism of the brain was a likely event in such cases, and he did not favour any more active procedure than firm bandaging of the calf.—Dr. WEBER said that the case was an example of a variety of malignant endocarditis which was invariably fatal, a matter to be considered in local treatment. —Mr. C. H. FAGGE asked whether it was agreed that the aneurysm was in connexion with the posterior tibial artery. He favoured the opinion that the embolism was in one of its muscular branches.

Mr. PHILIP TURNER and Dr. L. MANDEL showed a case of

Submammary Tumour of the Chest Wall.

The patient was a widow, aged 46, with one daughter, aged 18 years. She complained of a tumour in the region of the right breast, which had developed in the course of the past few months. About eight or nine years ago she received a severe blow on the right side of the chest from the open door of a moving railway-carriage. A swelling was noticed two or three weeks afterwards, and the doctor who was attending her told her that she had broken three ribs. This swelling never disappeared completely; some irregularity could be felt beneath the right breast, but she said that in appearance it was not different from the other side. About two or three months ago she noticed that the right breast was getting more prominent, and that there was a hard lump to be felt. She said that the present tumour occupied much the same position as the "irregularity" which persisted after the injury to the ribs. There had been little pain; her general health had not been affected, though she thought that she had lost weight to a slight extent, but the lump had steadily increased in size.

On examination the right breast was seen to be unusually prominent, and on palpation this was found to be due to a hard swelling about the size of a fist, which was adherent to the chest wall by a broad attachment. Its surface was lobulated and, especially on the outer side, it had an over-hanging edge. The skin was freely movable over the tumour and there was a good thickness, probably breast, between them. The nipple was normal and similar in appearance to that of the other side. The patient had had no cough, and examination of the lungs showed no abnormal physical signs. The tumour was considerably opaque to X rays, so that it was difficult to get a satisfactory view of the underlying ribs. There did not appear to be any destruction of bone, but the upper border of the fourth rib showed a clearly defined defect near the costo-chondral junction. Seen in profile the tumour showed some irregular ossification, not directly continuous with the ribs. It did not appear to extend into the cavity of the chest, and no intrathoracic abnormality could be seen. The X ray appearances suggested that the tumour was an ossifying chondroma connected with the fourth rib. The rapid increase in size favoured the probability of the growth being a sarcoma with secondary calcification and ossification, though the X ray examination, in the absence of any erosion of the ribs, seemed to be against this view.

Since the growth had not extended inwards, and as there was no indication of secondary growth or direct invasion of the lung, its removal was called for.

SECTION OF OPHTHALMOLOGY.

EXHIBITION OF CASES AND SPECIMENS.

A MEETING of this section of the Royal Society of Medicine was held on Jan. 14th, Dr. JAMES TAYLOR, the President, occupying the chair.

Foreign Body in the Eye.

Mr. G. WINFIELD ROLL showed a man who had had a Steel Fragment in the Eye 18 years. When seen by the exhibitor some weeks after the accident the vision was 6/6 and the media were clear. There was now a very small nebulous area near the limbus. As the foreign body was encysted, the vision good, and the eye quiet, he did not think there was any need for interference. Latterly vision was 6/18, but the eye gave no trouble, though an area of atrophy had appeared below the foreign body. Provided a foreign body in the eye was aseptic, he did not think there was any limit to the time it might remain in the eye.

Mr. W. T. HOLMES SPICER thought the slight changes seen in the choroid region might be due to the presence of the fragment, a local siderosis.

Large Inter-marginal Cups without Glaucoma.

Dr. A. HUGH THOMPSON showed a patient whose discs presented Large Inter-marginal Cups with, as yet, no signs of glaucoma. The patient, a woman aged 52, came for glasses; her vision was 6/12, she had lens opacities and hypermetropia. The eye tension was normal, and she never saw rainbow colours. The disc cups were now at a doubtful stage; some would regard them as glaucomatous, others would be uncertain whether they were physiological or glaucomatous.

Cases of Coloboma.

Mr. J. H. PARSONS showed a patient with Coloboma confined to the optic discs.—Mr. MALCOLM HEPBURN demonstrated a case of Coloboma of the Macula Region. There was a pearly-white centre, with a definite ectasia on the temporal side of the patch, and a border of pigment ran around the edge. Had it been an inflammatory patch there would have been more pigment proliferation. True coloboma of the choroid was very rare.

Photographing and Demonstrating the Interior of the Eye.

Professor SALOMONSEN, of Amsterdam, exhibited a series of ingenious instruments used by him for the purpose of demonstrating the interior of the eye to students, and also for obtaining photographs of the same.—Mr. A. C. HUDSON exhibited a new Perimeter.

The Bearing on Glaucoma of Deep Tension in the Eye.

Dr. RAYNER D. BATTEN gave a demonstration with two inflated rubber balls or balloons, one of which was covered with muslin, to show the importance of what he termed "deep tension" in the eye as indicating the onset of glaucoma. The deep tension in the eye was represented by the amount of dimpling which ensued with a definite fixed pressure. This deep tension, associated with a fairly deep excavated disc, was likely to merge into glaucoma.—Mr. M. H. WHITING and Mr. GRAY CLEGG (Manchester) discussed the question.

Mr. RANSOM PICKARD (Exeter) read a paper entitled

VARIATIONS IN THE SIZE OF THE PHYSIOLOGICAL CUP AND THEIR RELATION TO GLAUCOMA.

The cases he dealt with for the purposes of his thesis were a consecutive series, the only elimination being all possible cases of glaucoma and other diseases affecting the disc. He anticipated the objection that the subjects came because they had some affection of the eyes and were not simply part of the general population; still, the total numbers dealt with in the later age-groups corresponded very closely with the general population age-groups in Devon. Glaucoma was so rare under 40 years of age that cases might be taken, from this standpoint, as normal. The older the patient the greater the assumption that pathological changes had occurred, glaucoma accounting for a large proportion. Where necessary, the tonometer for pressure and the screen for the field of vision were employed. The disc and cup were carefully drawn in each case and transferred by means of carbon to graph paper. The area of each disc was then measured, and the results reduced to a percentage, 100 being taken as the area of the disc. The cases were grouped in ten-year periods. The myopic cases had large cups, though there were only two groups (16–25 and 26–35 years) in which the largest myopic cup was not exceeded by a hypermetropic cup.

Explanation of the alterations in normal disc cups involved, he said, many difficulties. An alteration in the size of a cavity, situated in a solid like the sclerotic and filled with a viscous fluid, might conceivably occur under three conditions: First, no alteration in pressure. Second, tension from without, as in the contraction or disappearance of nerve fibres or fibrous tissue. In this series cases of this kind were ruled out. Third, there might be pressure from within—i.e., pressure exerted by the vitreous, as in glaucoma. He submitted a twofold suggestion—that the tissues of all discs were not equally strong, and that small increases of pressure acting on the weaker discs over long periods might cause an enlargement of the cups in these cases, but not to the extent of interfering with vision.

Mr. Pickard proceeded to show, by means of the epidiascope, a comparison of the shapes of the glaucomatous and physiological cups. In the former there was certainly pressure from within. The glaucoma cup was usually a simple and symmetrical enlargement of the physiological cup; in a smaller number the conical enlargement was added on to the usual cylindrical form. If most of the glaucomatous cups were enlargements of the physiological cups caused by internal pressure, then presumably smaller degrees of pressure, acting on cups in which the tissues were weak, would cause smaller degrees of enlargement, and without, necessarily, deterioration in vision. Very varying degrees of tension came on in middle life without symptoms arising from it. Pressure was not the only factor, the resistance of the disc must be taken into account. Under the term glaucoma should be included only those cases in which there was sufficient pressure to interfere with the function of the organ; in the cases of high pressure without such interference the pressure must be regarded as a danger-signal. In these latter cases an accurate and thorough investigation should be periodically carried out and all predisposing causes as far as possible eliminated.

The author admitted that the main contention of this contribution, that there was a tendency for the physiological cup to enlarge with increase in age, was not proved but only inferred, but much might be done by a few cases being systematically followed through over a course of years, with accurate diagrams taken at regular intervals.

Discussion.

Mr. THOMPSON said this contribution supported the view that there was a distinct relation between a large physiological cup and a glaucomatous cup. In more than one case he had seen there was undoubted glaucoma in one eye and a large overlapping physiological cup in the other. Also, when ordinary glaucoma had occurred in one eye there was a considerable likelihood of the same condition developing in its fellow. The suggestion of the author that physiological cups were changed into glaucomatous ones owing to unequal resistance of the lamina cribrosa coincided with his own view. But he did not think that was the mode of causation in most cases. The ordinary glaucoma was that of the text-books, in which it began at the margin of the disc. He did not think the author had sufficiently emphasised the distinction between the ordinary shallow cup, which most discs showed, and the perpendicular cup, which latter often overlapped, so that the vessels came to the edge of the cup and disappeared from view, again being seen in the lamina cribrosa.

Dr. BATTEN thought what was required was some method of recording the cases of central cupping. The actual central cup he looked upon as comparatively innocent; it was when it got to the margin of the disc that it became dangerous. A combination of a large physiological cup and the existence of deep tension justified a fear of the supervention of glaucoma.

Mr. M. S. MAYOU pointed out the great difference between the physiological and the glaucomatous forms of cupping; in the latter there was an actual pushing back of the whole lamina cribrosa. Cupping was dependent not only on the intra-ocular tension, but also on the condition of the nerve fibres as they passed through the lamina cribrosa. He agreed that the danger was when the cupping passed to the margin of the disc.

Mr. N. BISHOP HARMAN continued the discussion, and the opener replied.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

AN ordinary meeting of this society was held on Jan. 21st at 1, Upper Montague-street, W.C., Dr. C. SANDERS (M.O.H., West Ham) being in the chair in the absence of the President.

Dr. G. E. OATES (M.O.H., Bethnal Green) read a paper on

Slum Areas in Central London.

He said that health officers, while approaching housing problems in a scientific spirit, must rely upon public opinion. The average London resident took little interest in the government of his borough. Great credit must be given to the press for the space devoted to housing questions of late, but the building of new houses appealed most to their readers. The slum dweller was not inclined to move to a cottage in the suburbs. Ex-Service men were now not so much concerned to get good surroundings as to get houses at all. The speaker referred to the distinction in size between London County Council schemes under Part I. of the 1890 Act and borough council schemes under Part II. The maximum number of houses for a Part II. scheme was now, he understood, held to be 150. He proceeded to indicate a few special types of slum areas, and mentioned that the only type which could readily be dealt with at the present time was the area containing vacant land which could be built on before any of the slum property was demolished. In regard to compensation, he was of opinion that Section 13 of the 1919 Act would have only a very limited application. Could we expect the Ministry of Health to agree to any compensation greater than laid down by Section 9? It was where the repair and renewal of old buildings went hand in hand with new building that the question of compensation became important. If the owner received nothing but the value of the land without buildings as a housing site or for an open space he would have a clear grievance if the houses were not all demolished. Owners might possibly put forward their present inability to demolish a dwelling house or dispossess their tenants as reasons for not making the houses fit. The economic questions involved in compensation were of great difficulty.

Dr. Oates then referred to the great difficulty of demolishing any area unless there was already accommodation to rehouse the displaced. Temporary accommodation or the conversion of large houses for the purpose was impossible owing to the incredibly high cost. It was undesirable to encroach on the public parks. The people could only be rehoused in high blocks of dwellings, which were undesirable. If slum areas could not be rebuilt at once, local authorities ought to decide and indicate their policy for the future. Owners might be willing to coöperate if they were assured there would be no demolition for a definite number of years. The speaker suggested that the L.C.C. and borough councils should collaborate with the Ministry of Health in a plan for dealing with unhealthy areas as a whole and from a national point of view. Closing orders at the present time were impossible. In most London boroughs little or nothing had been done under Section 28 of the 1919 Act and the Nuisance sections of the Public Health Acts remained the chief instrument for effecting improvements. The penal clauses in the latter were very effective.

Discussion.

Professor H. R. KENWOOD (M.O.H., Bedfordshire and Stoke Newington), in congratulating the reader of the paper, said that two factors which greatly hampered housing work at the present time were the impossibility of dealing with overcrowding, and the difficulty of remedial measures. Properties were deteriorating and also the people within them. The time was ripe for a conference of authorities on the subject. It was easy to exaggerate the importance of environment, and we should aim at helping, and, if possible, compelling people to make the best use of the accommodation provided. There had been in provincial towns a great exodus to the suburbs, but not in the case of the very poorest.

Dr. W. J. HOWARTH (M.O.H., City of London) referred to the results of the deliberations of the Slum Areas Committee, of which he is a member.

Dr. F. J. ALLAN (M.O.H., Westminster) remarked that new views on an old subject were always interesting. The new Housing Act added to the difficulties of M.O.H.'s. There was need of one authority for housing purposes for London and the surrounding country. The demolition of one slum commonly led to the creation of another. He hoped that good results might come from the formation of satellite towns around our big cities, comprising factories, &c., as well as houses, which would lead in the future to the emptying of the slums. Working-class people would not travel more than a limited distance to their work, and the Rent Restriction Act greatly restricted the freedom of those who did desire to move.

Dr. T. SHADICK HIGGINS (M.O.H., St. Pancras) referred to the present impossibility of preventing the overcrowding of houses, and the use as tenements of unwholesome underground rooms. It was a time for long views rather than immediate drastic action. It was most important that existing houses should not be swept away to make room for commercial premises, and for the growth of industry the creation of something like satellite towns was a necessity. He agreed with Dr. Howarth as to the injustice of allowing no compensation for all houses on an insanitary area. There was a gradation even in insanitary property, and there could not logically be drawn a definite line dividing off sanitary houses carrying a full economic value from insanitary houses having no value at all. While he agreed with Professor Kenwood that people of moral worth could make the most of even wretched houses, he was of opinion that the importance to the nation of good houses and other amenities could hardly be exaggerated.

Dr. T. S. MCINTOSH (M.O.H., Hendon U.D.) contended that the idea of effecting much improvement in housing at present was practically hopeless. Improvement schemes would reduce the number of houses available, and would replace cheap houses by dear ones.

The CHAIRMAN, in thanking Dr. Oates for his paper, remarked that a good deal of nonsense was being talked about housing. The danger lay in the overcrowding rather than in the structural condition of the houses. The new houses would become unwholesome if they were sublet so as to become overcrowded. Large slum areas had been formed in this way in the eastern suburbs of London in recent years.

Dr. OATES briefly replied.

Seventeen new members were elected at the meeting.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

A SPECIAL general meeting of this society was held at the West London Hospital on Jan. 14th, at which a discussion on

The Interim Report of the Consultative Committee of the Ministry of Health

took place. Dr. F. J. McCANN, the President, occupied the chair. Lord Dawson of Penn, who had intended to be present, was unavoidably absent.

Dr. F. G. LLOYD opened the discussion. He pointed out the importance to the whole profession of the subjects dealt with in the Report. He reminded the meeting that Lord Dawson had honoured the society by delivering the Cavendish lecture in 1918 on The Future of the Medical Profession. The present Report was largely the development of the framework contained in that lecture. Owing to increased expenditure many of the voluntary hospitals which previously on account of their endowments had not appealed to the public were now doing so. Their entry into the field had made it much more difficult for those which had hitherto depended entirely on the charitable public. Dr. Lloyd referred to the benefits that "team-work" would give to the public and the help that the general practitioner would receive from it. He urged the profession to concentrate their efforts to procuring by this means all the help that modern research could give. He pointed out that in this respect we were not as up to date as such countries as Switzerland, America, and France. He was strongly in favour of the retention of the voluntary system as opposed to State control. He suggested that the retention of the voluntary system would constitute the best possible "war memorial" to those that had fallen. It would require the united and concentrated effort of the medical profession and public to ensure the salvation of the voluntary system.

Dr. C. W. HUTT (M.O.H., Richmond, Surrey) wished to emphasise the help that bacteriology affords in the diagnosis and treatment of disease, and urged that it should be brought to the door of the practitioner. He thought that Lord Dawson's scheme was an excellent attempt at constructive work, and that by affording the practitioner bacteriological help both the general public and the practitioners would materially benefit by it.

Lieutenant-Colonel E. M. WILSON was opposed to State control of the hospitals, and considered that a great deal might be done to relieve the financial position of the hospitals by instituting some system of voluntary contributions from the patients. This was already at work in some of the hospitals and had proved very satisfactory. He thought that contributions according to the financial position of the patient were better than a "flat-rate" system, and he hoped that if some such scheme was adopted the hospitals might thus avoid the necessity of State aid, which must necessarily involve some amount of control in the management.

Dr. T. ORR (M.O.H., Ealing) said that we had first of all to consider whether the medical treatment provided for the people of this country was sufficient. The examination of recruits during the war showed the great amount of preventable disability that existed, and it was largely on account of this finding that the Ministry of Health was established. The Consultative Committee had the duty of advising the Ministry as to the best methods for preventing the continuance of this serious state of affairs. The Dawson Report was the result. He thought that the scheme proposed would cost an enormous sum of money, and it was our duty to consider whether it should be adopted in whole or part.

Dr. RICKARD LLOYD referred to the question of remuneration for the members of the profession engaged in the Ministry's scheme, and questioned what would be the future field of general practice. If the time of the general practitioner was largely taken up by Ministry of Health work it would be interesting to know what time would be available for private practice.

The PRESIDENT said there appeared to be a general desire to see the voluntary system of hospital administration continued in this country. He thought that State control should be strenuously opposed, as it would not make for the advancement of science. In his opinion "team-work" was essential if the patients were to obtain the maximum benefit from scientific medicine. He thought that the scheme set out by the Ministry of Health would be very costly, and that the tax-payers would refuse to contribute the money. He pleaded for the establishment of maternity hospitals and centres without delay, and pointed out the grave necessity for these in the country. The future of the nation depended on the birth-rate, and money could not be better spent than providing a thoroughly efficient maternity service. This, he thought, should be State-aided.

SOCIÉTÉ DE THÉRAPEUTIQUE DE PARIS.

AT a recent meeting of this society Dr. ARTAULT DE VEVEY read a paper on

Lymphotherapy in Puerperal Fever.

The method consists in injecting the patient's own serum obtained from a blister. He stated that he had employed the method in nearly a thousand cases of infectious disease, especially influenza, as well as in other conditions, probably of an infectious character, such as rheumatism, herpes zoster, chorea, facial neuralgia, appendicitis, and metritis. The method had proved to be most successful in definitely infectious diseases, especially of a febrile character, and had never produced any unfavourable results.

Treatment of Broncho-pneumonia by Formation of a Tracheal Fistula.

In his paper Dr. G. ROSENTHAL stated that this method should be employed early and energetically so as to prevent secondary localisation, as it was ineffective in septicæmia accompanying a pulmonary localisation. On the other hand, as long as the disease remained local it was capable of effecting a cure. Injection of gomenol oil was the usual procedure, to which should be added taurocholate of soda, which had a liquefying action on the pneumococcus. In desperate cases oil of turpentine, in doses of 1–2 c.cm., could be used.

Dr. M. TIFFENEAU and Dr. BOUCHEREAU communicated a paper on the

Combination of Phenols with Hexamethylenetetramine.

The most important preparation according to them was the diphenate, which possessed in a modified form all the properties of its principal constituent, phenol. On the other hand, it had no caustic action and was slightly less toxic, while its antiseptic power was slightly but definitely superior to that of phenol.

Opotherapy in Dementia Præcox.

Dr. A. MARIE (de Villejuif) in his paper reported seven cases of dementia præcox in women and girls, accompanied by disturbance of the ovarian functions, whom he had treated with ovarian extract, combined at a later stage with thyroid extract. In four recovery took place, and had lasted for one, two, three, and five years respectively. In two other cases improvement had taken place, but it was too early to say if recovery would be permanent.

Treatment of Erysipelas in the Newborn.

In this paper Dr. R. LABBE and Mme. M. DE LARMINAT recommended swabbing the affected areas four-hourly, however great their extent, with a 1 in 400 watery solution of silver nitrate. The skin should then be allowed to dry, and be sprinkled with an aseptic powder, such as salicylated talc. The treatment should be continued until recovery, in spite of the brown pigmentation of the skin. No bad effects had been observed.

Dr. L. CLAP read a paper on the

Treatment of Chilblains,

in which he stated that during the war he had several times relieved the pain caused by this affection in soldiers with an elastic bandage applied either directly over the chilblains or just above them. The results were equally good in both cases. Local compression acted more rapidly, but was more painful, while the effects of compression at some distance from the chilblains were more lasting. The former was indicated when there were only a few lesions on the fingers or sides of the feet, while the latter should be reserved for multiple lesions, chilblains on the toes, or ulcerated lesions.

Reviews and Notices of Books.

SURGICAL ASPECTS OF DYSENTERY.

By ZACHARY COPE. London: Frowde, Hodder and Stoughton. With 2 coloured plates and 19 illustrations. Pp. 147. 12*s.* 6*d.*

WITH the termination of the war an increasing number of men who have been exposed to the infection of dysentery are returning to England, so that it is probable that the late stages and complications of this disease will be seen not uncommonly. The majority of English physicians and surgeons have had but little experience of this disease, and will probably find considerable difficulty in its diagnosis and treatment. This monograph will come as a real help to them. It is small, clearly written, easy to read, and yet contains an astonishing amount of information. So helpful is it from the surgical point of view that the only feeling that is left after reading it is one of disappointment that the medical aspects of the disease have not been dealt with in the same or a similar volume; for they also will present difficult problems in the near future. Especially would we have liked to have seen a wider discussion of the relative frequency of amœbæ and the various bacilli as causative factors. The surgeon's need of some medical knowledge of the disease is emphasised in the first chapter, which discusses the frequency with which dysentery occurs as a complication of, or simulates, some surgical lesion. The description of the surgical complications occurring in the early stages of dysentery is very useful, and stress is laid upon the difficulty in distinguishing between true appendicitis and dysenteric typhlitis—a distinction which is of very considerable importance in the question of treatment and progress. It is interesting to note that more active surgical steps are advocated in cases of chronic infection when, as the author points out, the whole colon may be converted into a pus sac. Up to the present these cases have been so rare that the treatment has not been clearly defined, but many of them could doubtless have been saved by more active surgical measures than those usually adopted. Mr. Cope's experience certainly supports this view.

A large section is given over to the consideration of amœbic hepatitis and liver abscess, and the only criticism we would offer on this section is that the division into chapters is artificial and somewhat confusing. Stress is laid upon the importance of early treatment with emetine, but although it is pointed out that the use of this drug may rapidly cure hepatitis, and that it should always be administered after the abscess has been drained, its value as a method of treatment alternative to operation is not discussed. Yet there is a certain amount of evidence that even when a definite abscess has formed it may be cured by emetine alone, and it would have been interesting to read Mr. Cope's view on this point. The relative value of the different forms of treatment is ably dealt with. Mr. Cope does not favour washing out the abscess cavity with quinine, as he has found that emetine by mouth is as efficacious in destroying the amœbæ. The last chapters of the book are devoted to a description of the rarer complications, many of which are rather more medical than surgical. To all those who may have to diagnose and treat these cases—and who, indeed, may not have to do so to-day?—the book will be of great value.

DIE CHIRURGIE DER BRUSTORGANE.

By FERDINAND SAUERBRUCH. Berlin: Julius Springer. 1920. With 637 illustrations. Pp. 931. M.240.

IT is well known that Sauerbruch has been interested in thoracic surgery for many years. Many surgeons will remember his earlier work, published in 1911, which did much to stimulate interest in a field of surgery which at [illegible] time was hardly touched. He has now produced a large volume, in association with several others, in which he presents with great detail the anatomy, physiology, pathology of chest complaints, together with the surgical treatment as far as it can be carried out. The book is by no means intended for the use of surgeons only, for its survey includes all methods of treatment, and Sauerbruch expresses the hope that physicians as well as surgeons will read it. That the book is a large one and a monument of industry may be judged from the fact that the bibliography alone runs into 47 large closely-printed pages.

The plan of the book is as follows: A long chapter on the anatomy of the thorax; then is given the physiology of respiration and a chapter on the general pathology of diseases of the thoracic viscera; after this comes what is perhaps the most important part of the book—namely, a long and well-illustrated chapter on diagnosis by means of X rays and clinical methods. Then come shorter chapters on anæsthesia, the use of pressure chambers for obviating pneumothorax, the methods of opening the thorax, and the general technique of thoracic surgery. The second part of the book deals with special forms of injury or disease, each group being dealt with separately; considerable attention is paid to deformities of the chest, and wounds of the lung, abscess, bronchiectasis, and tuberculosis are examples of the subjects considered.

The book is an extraordinarily good one, its merit lying in the breadth of its outlook as well as in its attention to detail. Its outlook includes the history of chest surgery and the fundamental sciences of anatomy, physiology, and pathology, whose handmaid surgery must always be. Some 200 pages (nearly a quarter of the book) are devoted to "diagnosis." It is a truism to insist on the need of a correct diagnosis as a prelude to any form of treatment: in thoracic work the difficulty of obtaining this has been one of the great obstacles to advance. It is only recently that we have been able to make a little progress with the help of X rays, and even now the correct interpretation of the pictures obtained is by no means easy. The diagnosis of abdominal complaints is far more advanced, for the reason that opinions have been checked and corrected by observations made after opening the abdomen; if the hopes and aspirations of thoracic surgeons are realised, and when an exploratory thoracotomy becomes as usual and safe an operation as exploratory laparotomy, then, and not till then, will our diagnosis become more sure. Physicians should be interested in the chapter on the treatment of tuberculosis, and especially to that part referring to the formation of artificial pneumothorax—this is a point which has been, perhaps, too much neglected by English surgeons; it merits their attention. Sauerbruch is a believer in the use of a pressure chamber in all cases in which the chest has to be opened. He holds that the risk of serious interference with the respiratory mechanism is diminished in that the operation can be performed with greater ease and comfort, and that on completion of the operation the lung can be inflated and the chest closed without leaving a pneumothorax. In this country surgeons have not been advocates of the pressure chamber, they believe it unnecessary and rely on gas and oxygen anæsthesia or intratracheal insufflation. At any rate, English surgeons have demonstrated that chests can be opened and operations safely and satisfactorily performed in this manner, and during the war, both in the French and English medical services, hundreds of chests were opened under general anæsthesia without any special form of pressure chamber or insufflator. Not the least interesting part of Sauerbruch's book is the article on gunshot wounds of the chest. He is a conservative surgeon whenever possible, emphasising the importance of rest for all lung wounds. He is insistent, however, on early and free operation for severe bleeding or increasing pneumothorax. It would be interesting to learn what was the practice of the German medical service as a whole on this subject.

This book is the best at present existing on thoracic surgery and the most important contribution to this line of work that has been made for several years.

THE NEW EDUCATION.

A Critical Presentation of the New Education Scheme of the London Education Authority. By L. HADEN GUEST, *M.C.*, M.R.C.S., L.R.C.P. London: Hodder and Stoughton. 1920. Pp. 118. 2*s*.

IN this concise little book Dr. Haden Guest gives an analysis of the main points in the London County Council's new scheme of education from the nursery school to the university, although there is very little in the book about the latter or the training of teachers. The public as a whole will be glad to know that no more school buildings of the heavy three-decker type, costing so much to build and so much to alter, are to be erected. The new schools are to be of the open-air type and of lighter and cheaper construction. School journeys, which do so much to improve the health of the children, taking them to the country or the seaside for a week or more, are to be encouraged, and will become a more outstanding feature in the elementary school curriculum.

Dr. Guest regrets that the Council have not yet seen their way to include spray or shower baths in the plans for the newer schools or to establish them in the older ones. He maintains that the provision of baths would effect an improvement in health, and consequently in attendance, in addition to greatly reducing the vermin infection which still attacks a very large proportion of children. In this way, he asserts, we could dispense with the expensive cleansing stations "which 'keep down' vermin infection but do not prevent it as a training in cleanliness would." Medical inspection is to follow the child into the continuation school, as it does at present into the secondary school and training college, and facilities for treatment are to be available. A special medical examination of children between 12 and 14 employed out of school is to be made. Dr. Guest considers that while provision for the mentally and physically defective child is on the right lines, the Council has not seized the opportunity of dealing with the problem of the industrial and reformatory schools. He states that in spite of the improvements made in these schools in the last few years, the whole provision is at present unsatisfactory and will not really improve until the system as a whole is lifted out of the "criminal" atmosphere into that of the purely medical and educational. Nursery schools are dealt with sympathetically by Miss Margaret McMillan, who deplores the timidity of the Council in this direction.

The book is a critical survey carefully written and deliberately constructive in tone.

THE PRINCIPLES OF PREVENTIVE MEDICINE.

By R. TANNER HEWLETT, M.D., F.R.C.P., D.P.H., and A. T. NANKIVELL, M.D. Lond., D.P.H. Camb. London: J. and A. Churchill. 1921. Pp. 536. 21*s*.

THE general practitioner has always been and must always be the most powerful agent for promoting the health of the community. His advice is constantly being sought not only as to the treatment of disease, but as to the maintenance of health. The present trend of the public health service, which is to develop more and more the personal side of its work through centres for maternity and infant welfare, school clinics, and the like, make it a matter of pressing importance that the busy practitioner should have available information as to these developments and their relation to his daily work. Medical students receive but imperfect instruction on these matters, while those already in practice find difficulty in keeping themselves acquainted with modern advances. A book intended to provide the necessary information has just been published. There can be little doubt that such a book is needed, and fortunately this book is well written, presents no extreme views, and, when the authors are dealing with subjects particularly their own, provides attractive reading. On the other hand, certain subject-matter appears to have been got up for the occasion, such, for instance, as that on industrial hygiene and vital statistics. Neither is dealt with adequately, and both might advantageously have been omitted.

The authors aim at stating clearly great principles and avoid overwhelming their readers with detail. Housing is deservingly dealt with somewhat fully, and the fundamentals for healthy dwellings are admirably given without being obscured with constructional items of interest only to a builder. Vivid word-pictures are used freely and with some advantage. Of the old system by which human excrement is "conserved" in pails and tubs, they say: "The most loathsome and bestial conditions of life exist among these 'conservancy system' houses. ...... These deadly places beggar description, since it is not possible for the pen even to adumbrate the horror of the smell in all its sickly sweetness of putrescence." We should to-day build for future generations. "When we look upon our towns and slums we can only deplore the meanness of the minds that designed them, and let us hope that our descendants will not be able to say this of us." The suggestion that the ideal city should be one of 50,000 inhabitants spread over about 3½ square miles of country recalls the recommendations in Aristotle's republic. The sections dealing with infection and infectious diseases give an admirable summary of present knowledge plainly expressed with the introduction of a minimum of abstruse nomenclature; even immunity is discussed without reference to "complements" and "amboceptors." Similarly a broad and interesting sketch is given of infant and school life, of infantile mortality and juvenile disease; the aim throughout being to lay stress on prevention of those disturbances of health which become the beginnings of disease. We cannot refrain from quoting, in relation to the condemnation of barley-water and pap as nourishment for infants, the remark that "if Nature had intended them to be a baby's diet, she would, no doubt, have provided the mother with barley-water in one breast and rusks at the other," and also "there is death in the pot, and the platter kills more than the sword."

One criticism must be made with reference to death-rates, a criticism which also applies to other writers. The student unaccustomed to statistics should be presented with rates having a common denominator, and the usual one of 1000 population should be strictly adhered to; but while the general death-rate is so given, we find the death-rate from diphtheria stated per 100,000 population, and that from tuberculosis, influenza, cancer, and other causes of death, per million. Confusion is bound to arise from thus altering the denominator, and no advantage is gained by moving the decimal point this way or that. The book is well printed and possesses an adequate index, and we have no hesitation in recommending it to the attention of the profession.

WOCHENBETT-UND SÄUGLINGSPFLEGE.

Von Prof. Dr. EDUARD MARTIN. Berlin: S. Karger. 1920. Pp. 96.

THIS little manual for mothers and midwives was designed to meet the need for a simple text-book dealing primarily with the puerperium and the care of the new-born infant, which, without being overloaded with detail, should yet give all the information necessary for the intelligent treatment of mother and child. The author appears admirably to have succeeded in this attempt, the essential points connected with the normal puerperium being given in the simplest possible language. The teaching is eminently practical throughout, and the 47 woodcuts, though somewhat crude, add value to the book. The question of the feeding of the infant is carefully gone into, and some of the difficulties connected with breast feeding are discussed. Although not much space is devoted to pathological considerations, the author explains clearly the danger-signals of many of the puerperal diseases, pointing out that none of them falls suddenly like a bolt from the sky.

Altogether this small volume, which has an adequate index, should prove of real service to mothers and midwives.

NURSING OF CHRONIC PATIENTS.

By ELEANOR C. BARTON, R.R.C. London: The Scientific Press. 1920. Pp. 126. 1s. 3d.

THERE are few branches of nursing which test the skill, character, and mentality of the trained nurse more exhaustively than does the nursing of chronic cases. Miss Barton in this small handbook gives many valuable hints which should be helpful to young private and district nurses whose past experience has been with hospital patients suffering from acute diseases. Although the book, as a contribution to nursing literature, is slight, it has obviously been written by one with a broad knowledge of the nursing of chronic patients and of the true value such nursing can prove if undertaken with enthusiasm and the determination to alleviate the irksome discomforts so often accompanying protracted illness. The nursing points suggested in cases of hemiplegia and paraplegia are specially valuable and cannot be over-emphasised, and if the nursing of chronic patients is carried out in the spirit of helpfulness which pervades this book such work should prove of considerable interest and its tedium be greatly alleviated.

JOURNALS.

Quarterly Journal of Medicine. Edited by J. ROSE BRADFORD, A. E. GARROD, W. HALE-WHITE, R. HUTCHISON, H. D. ROLLESTON. October, 1920. Vol. XIV. No. 53. Oxford: At the Clarendon Press. Subscription 25s. per annum.—The importance which chemical pathology is playing in present-day medicine is well illustrated by the composition of the current number of the *Quarterly Journal of Medicine*. There are five papers in all and every one is concerned with a question of chemical pathology. The first article by Dr. Reginald Miller and Mr. Herbert Perkins consists of a clinical and analytical study of a case of congenital steatorrhœa. The only case hitherto recorded was reported by Professor Garrod in 1913. The authors are not able to say wherein the error responsible for the fat wastage lies, but there is no evidence in their case of pancreatic disease as adduced by the usual tests. A study of their case appears to confirm Garrod's suggestion of "an inborn error of metabolism probably due to the absence of a normal enzyme, presumably a pancreatic enzyme. It is difficult to believe that there is any real disease of the pancreas."—Dr. George Graham contributes the results of a research into the source of the uric acid excreted after the exhibition of atophan. He concludes that the "extra" uric acid excreted in the urine cannot come solely from the blood, but is probably also derived from uric acid in solution in the tissue fluids of the body. As drugs like atophan, aspirin, sodium salicylate, and sodium benzoate only cause an increased output of uric acid for two or three days, it is useless to give them for this purpose for long periods. If given to gouty people two or three days each week or fortnight it would seem possible to prevent any great accumulation of uric acid in the body, and in this way to ward off attacks of gout.—Dr. Dennison V. Pickering publishes the results of many observations on the blood-sugar in diabetes. From his conclusions it appears that a case with a high blood-sugar content which can be reduced by restricting carbohydrate will probably show greater carbohydrate tolerance, and therefore will do better than a case with a lower blood-sugar content not affected by diet.—Dr. Mackenzie Wallis writes on the "Diagnosis of Diseases of the Pancreas, with Special Reference to Diastase in the Urine." He concludes that an increase of diastase in the urine, together with the presence of glycosuria and a positive result from Loewi's adrenalin mydriasis tests, affords strong evidence of pancreatic disease and that this is still further strengthened if creatorrhœa and steatorrhœa be present.—Dr. E. Wordley discusses the effect of high protein diet on albuminuria and blood urea in cases of chronic nephritis. His results are full of interest. In chronic cases it appears that variations in the amount of protein in the diet have no effect on the amount of protein excreted in the urine. In fact, such increases in the diet do not increase albuminuria; if only percentage figures are taken they may decrease it owing to the diuresis produced by a rich protein diet. It is shown that the blood urea varies very considerably with the diet, and that an estimation of the blood urea is of much less value in appraising the impairment of renal function than Maclean's new urea test. Further, the blood urea may be within normal limit and yet all the manifestations of uræmia be present.

The Military Surgeon for December, 1920, opens with a very readable paper by Captain Wesley C. Cox and Major H. Wood on the hydrogen-ion concentration of media and on buffered solutions whose reaction changes but slowly. There is a chart of the colour reactions of indicators and an account of a simple and convenient colorimeter. The U.S. Army Medical School, anxious that the media used in its associated laboratories shall all have identical reactions, sends out standard phenol-red tubes as controls, and these, if sealed in best quality glass-tubes and kept in the dark, are permanent for some months.—Mr. E. V. Cowdry begs that the nations, for Christian charity's sake, shall seek to arouse in China a zeal for preventive medicine, and details what is being done for medical education in that great empire by China herself, by foreign powers who are supporting medical schools, and especially by the Rockefeller Foundation, which has spent a million and a quarter pounds on the Union Medical College in Pekin. But there are only 600 first-year medical students in all China.—Dr. C. H. Moore and Dr. A. de F. Smith, who were working with the U.S. Army at Coblentz after the armistice, urge that in large centres fractures should be treated by specialists, that in any case they should be treated immediately in spite of swelling, that X ray control is necessary, and that every hospital should have a portable X ray outfit. The splints required are few, combined traction and suspension are the methods of choice, after-care is most important, and their message is that massage, electrical treatment, and occupational therapy must be available in hospital.—Dr. Martin B. Tinker also insists on the value of war surgery in civil practice, advocating wound excision (which he recommended in 1909) in industrial surgery. He stains the wound with iodine and carbolic acid, removes damaged tissue ("nearly always more tissue lives than we expect"), at the same time does any plastic repair that is necessary, transplanting fat to avoid adhesions, and using Carrel tubes and solution to avoid sepsis.—Major F. Kramer tells how the U.S. Army Medical Corps demobilised its patients last year, reducing its hospitals from 55 to 8, its beds from 64,000 to 7000, and its sick from 40,000 to 5000, working from a state of specialism and subdivision to one of general utility and consolidation. Of 18,000 fresh cases diagnosed as tuberculous 4305 were unconfirmed, and of these many were residual pulmonary infections, sequelæ of influenza.—Lieutenant-Colonel Louis C. Duncan relates the history of the preparation of the great "Medical and Surgical History of the War of the Rebellion," 1860-64, which was not completed until 1888, by which date many of its contributors had died. We rarely hear any whole-hearted admiration expressed for service life and methods. That makes the more interesting an article by Captain E. Colby, who appears to be on the teaching staff of the University of Minnesota. In the army he was for a time commanding a company, and for another period on the staff. He learnt the importance of attention to administrative detail and the uses of red tape; he learned that rules are not made to be broken, and he realised that the teacher was responsible for the success or failure of the taught. He was responsible for the pay of his men, and had to keep their accounts accurately. He had to render reports, and these punctually and without mistakes. On the staff he learned the value of reports. He found that rules are made to save time, to facilitate simultaneous coördinated action from a team, and so to increase output. He observed that instruction in drill must be clear, simple, brief, and graduated—every man must be sure of the foundations before going further. An officer is judged by his results. "Awkward" men must not be allowed to remain "awkward," they may disgrace the whole regiment. He concludes: "Like the company commander, the teacher should be judged by his results. This belief I acquired in the army." "Howlers," being a proof of misunderstood teaching, are, he thinks, a disgrace to the teacher rather than to the taught.

Maternity and Child Welfare. Vol. V. No. 1. January, 1921. —This journal is now the official organ of the Central Council for Infant and Child Welfare. In the January number Miss Hilda Cashmore writes on the Community and the New Social Worker. She points out that a serious confusion of thought has given rise to a new label of "social worker," which includes an almoner, a health visitor, and a secretary of the C.O.S., but excludes a doctor or a district nurse. Dr. Leonard Findlay pleads for a pure milk-supply, the notification of venereal disease, and the education of the parents of to-morrow as necessary parts of an intelligent campaign to reduce infant mortality. Suggestions for infant welfare work in Czecho-Slovakia, by Miss M. Payne, are quoted elsewhere in this number, also notes on recent developments in Finland, France, and Serbia. The methods adopted by the Child Health Organisation, U.S.A., in teaching children under 10 years of age are discussed; the staff includes a "health clown," combining entertainment with instruction, a cartoonist, and a "health fairy"—a trained nurse in disguise. The terms of reference of the Executive Committee appointed in March, 1920, and the report recently submitted by this committee to and adopted by the Central Council for Infant and Child Welfare are given in full in this number.

THE LANCET.

LONDON: SATURDAY, JANUARY 29, 1921.

Foot-and-Mouth Disease.

Foot-and-mouth disease has assumed considerable importance in this country lately on account of the severe outbreaks that have occurred in Kent, in Gloucestershire, and then in the Midlands, where great inconvenience was caused to business during the Christmas weeks by reason of restrictions imposed by the Ministry of Agriculture, and later in the West Riding of Yorkshire. Thanks, however, to the measures promptly undertaken by the Ministry's officials the disease seems now to have abated, although five more outbreaks occurred the week-end before last, and one was reported this last week in Herefordshire. In the Midlands the outbreak became the gravest that had been known for 30 years, and its wide and rapid spread aroused a very impatient mood among stock-owners. It would appear that the disease, after making its appearance in the West of England, became transported to the Midlands on account of movements of animals to supply the Christmas markets, especially that of Birmingham. In their anxiety to make adequate arrangements for meeting the Christmas trade stock-owners and dealers were not sufficiently careful to observe the condition of health of the cattle in their charge, with the result that animals affected with the disease were mixed with healthy stock, exposed at public markets, and redistributed over wide areas, thus rendering the whole country liable to the risk of infection. Last week an outbreak was reported in Ireland, which had been free since 1914.

Foot-and-mouth disease, as the name implies, is a condition in which lesions are produced about the feet and in the mouths of ruminants—cattle, sheep, and pigs in the respective order of importance. Other animals may also become infected, but the lesions produced are usually not such as to cause serious inconvenience. The lesions take the form of vesicular eruptions within the epidermis, these starting in the form of small congested points, which soon become converted into vesicles by exudation of serous fluid. By confluence vesicles of considerable size may be formed, especially on the tongue, and when these burst, as they quickly do, large patches of epidermis may be denuded. In the mouth the lesions are found on the tongue and buccal mucous membrane, gums, and sometimes in the pharynx. The irritation caused by their presence produces intense salivation, and the saliva discharged by the affected animals is very markedly infective. The lesions about the feet are of the same nature and occur in the skin just above the hoof or behind the claws, and cause great lameness. Sometimes secondary necrotic changes set in, and sloughing of parts of the tissues or even of the whole hoof may take place. Vesicular lesions sometimes appear on the udder and teats of milch cows, and cases of, or even outbreaks of, the disease have been recorded in man through the *drinking of milk* from cows so affected or through the operation of milking. The period of incubation is usually 2–7 days, but may extend to 11 days. As a rule, the animal recovers fairly quickly; the lesions heal in 5–6 days, so that an animal recovers in two or three weeks. The average mortality in an outbreak does not exceed about 5 per cent. In young animals, however, calves and lambs and young pigs, a rapidly fatal type of the disease is often seen in which the animal succumbs *after an acute febrile attack without the development of local lesions.* Post-mortem, petechiæ on the heart muscle form the most marked lesion. Sometimes animals may become affected with an intense gastro-enteritis. The local lesions, especially the foot lesions, may sometimes lead secondarily to marked necrosis of the surrounding tissues, which may ultimately involve destruction of the animal. The cause of the disease is an ultra-visible or filtrable virus, found in the serous exudate of the typical lesions and in the saliva. It is also said to be present in the blood during the febrile stage preceding the development of the local lesions. The disease can be set up by means of infinitesimal quantities of the virus, so that this disease is perhaps about the most contagious one known. The virus is not highly resistant towards external influences, and at ordinary temperatures, when exposed to daylight and allowed to dry, it loses its virulence in about 24 hours. On the other hand it has been kept alive for as long as three or four months in sealed tubes in the dark. It is quite sensitive to the action of heat and disinfectants. In countries where the disease is allowed to spread unchecked it remains enzoötic, and after suffering from the disease once the animals usually remain free for a year or two. The immunity, however, set up by one attack is short-lived, and cases are on record where the disease has been known to affect animals a second time within about two months after the first attack. In these backward countries the disease is conveyed by the ordinary means of contagion, principally by contact with affected animals or with food or other materials soiled with the infective discharges. On the Continent restrictions are placed in most countries upon the movement of stock out of or into the infected premises, but on account of the high contagiousness such precautions are only partially successful. In this country, thanks to the measures carried out by the Ministry of Agriculture, which has powers to make orders to deal with the disease under the Diseases of Animals Acts, and thanks also to the prohibition of importation of animals except for slaughter at the port of entry, we have been comparatively free for about 35 years, only local outbreaks having been recorded. Prior to the adoption of these measures extensive epizoötics used to occur from time to time, such as in 1869–1872 and 1881–1884, when hundreds of thousands of animals were attacked; in the year 1883–1884 there were 18,732 separate outbreaks in Great Britain, spread over 75 counties, and affecting nearly half a million animals. The disease first made its appearance in this country in 1836, although the flocks of Europe had previously suffered. Since the time when the late Sir GEORGE BROWN and the Veterinary Department of the Privy Council rid the country of the disease in 1885, the 95 outbreaks in 1892 are the only ones comparable to those that have occurred in the past two years.

The success of the policy adopted by the authorities depends upon prompt reporting of suspected cases; the police are informed and communication is established at once with the veterinary staff of the Ministry, and an official is immediately despatched to the spot to investigate the condition. If the outbreak should turn out to be one of foot-and-mouth disease all affected animals are slaughtered immediately and buried or burnt, and all in-contacts or suspected in-contacts are likewise slaughtered. An area with a radius of about 15 miles from the affected centre is then declared, and movements of animals are prohibited strictly into or out of this area, and even within the area, except for immediate slaughter. This policy at first sight appears drastic and costly, especially in view of the fact that the disease is seldom fatal. However, this policy resolutely carried out by the Ministry, with the active coöperation of stock owners and other interested parties, should have as its effect the obliteration of an initial outbreak and the prevention of the establishment of secondary centres. The loss entailed by wasting in condition of animals during an attack, and by the total cessation of the milk-yield in milch cows would undeniably exceed to a tremendous extent the monetary losses now involved in carrying out the policy and in giving compensation to owners. In countries where this disease is enzoötic, treatment of the lesions is adopted and various remedies have been boomed as specifics. At the most these can only be regarded as palliatives, and upon careful investigation they have been all found to have no specific action. A serum can be produced, which has some value as a preventive, by hyperimmunising cattle with material from the lesions or with blood of affected animals during the febrile stage. In France and in Argentina the serum has been shown to have some economic value, but it is costly to produce and the immunity is a short-lived one; and in any case it does not meet the need for stamping out the disease.

Now comes a most important question. How can we explain the periodic appearance of the disease in this country? The reason for most of the recent outbreaks can be seen; they are secondary outbreaks due to the movement of infected cattle. But we are at a loss to account for the epidemics which occur from time to time when the country has been free from the disease for some considerable time or when they happen at distances far apart or in circumstances which seem to exclude all chances of mediate contagion. We know that such initial outbreaks do occur on farms where there has been no movement of animals into or out of them for some time. In making a survey of the position as regards this country during the 20 years prior to Sept. 20th, 1920, the Chief Veterinary Officer of the Ministry of Agriculture, Sir STEWART STOCKMAN, computed that there had been no fewer than 63 such initial outbreaks. Examination of the facts revealed that none of the mediate means of contagion such as would account for the *importation of other* infectious diseases—for example, anthrax—could be held responsible for the sudden appearance of the disease. Anthrax is known to be imported in most cases with infected material. But the importation of feeding stuffs, manures, or packing stuffs from the Continent could not be responsible for the foot-and-mouth epidemics, neither could the movements of human beings to and from the Continent. Two theories remain—viz., that the disease is r-borne, either by the winds or by birds. We ow that the disease is carried considerable distances in the direction of a strong prevailing wind, and that these initial outbreaks occur when the disease is propagating to a serious extent in neighbouring parts of the Continent. If the incidence of this disease is examined by counties or groups of counties we see that certain groups are particularly liable to be "hit," while others remain free. It is suggested as possible that there may be some atmospheric condition in the nature of air pockets which prevails over the areas predisposed to attack. The bird theory is not favourably countenanced inasmuch as the incidence of attack does not correspond with the migratory periods of birds. Recently a Departmental Committee was formed to suggest measures for investigating the causes which give rise to outbreaks of the disease, and we understand that upon the recommendations of this Committee experiments are now being carried out in mid-ocean upon ironclads under the supervision of the renowned bacteriologist NOGUCHI. We are awaiting with great interest the results of his investigations.

The Census.

UPON the eve of a Census we must expect the time-honoured jests regarding statements of age by maiden aunts and the difficulties of an uneducated householder faced by the lengthy schedule. These weary witticisms are again in the newspapers, but phrased more bitterly than ten years ago; one journal has already hinted a doubt whether the employment of hundreds of clerks and the expenditure of hundreds of thousands of pounds upon a Census is worth while. "Where are thy Batches?" howled the people. "Hungry *canaille*," asked FOUQUIER, "is thy bread cheaper, wanting them?" One gathers that the official statistician, the "bureaucrat," or "*squandermaniac*," is hardly more popular than was FOUQUIER, and it may be worth considering whether he could provide a better answer to a similar question regarding batches of abstract, or arithmetical, heads. Perhaps the best answer is to recall events of 100 years ago, of a period of transition bearing some resemblance to that of to-day.

Following the last great European war there was a social and economic upheaval. Then, as now, there were heavy taxation, much distress, and the future was uncertain. At that period came the first collective attempt to appraise the results of the industrial revolution which had changed England from an agricultural to a manufacturing country. The relation between industrial employment, the housing and the feeding of the labouring population, and the national health were prominently discussed. Did work in factories injure the health of the employees? What was the relation between insanitary surroundings and longevity? Were towns more unhealthy than the country, if so, how much more unhealthy? All these questions then, as now, were eagerly canvassed, and the evidence submitted to Royal Commissions and Parliamentary Committees between 1820 and 1840 covers thousands of pages. What impresses the modern reader most is the logical inadequacy of the evidence. Hundreds of statistical tables were printed comparing, *for instance*, the mean ages at death in different localities and *different occupations*; from such tables sweeping conclusions were drawn. Dr. FARR'S witty comment that "if the inquiries had been extended to boarding schools or to the boys at Christ's Hospital the mean age at death would have been found still lower"; seems to modern readers to indicate an extremely low average level of statistical logic amongst his contemporaries. But, in fact, the users of these fallacious arguments were not fools; they used bad statistics because they could get no better statistics. At the Census of 1831 the age-distribution of the population was not obtained, and it was not until after 1841 that deaths at ages could be properly related to local populations at risk in different areas. It is not too much to say that the defective statistical machinery, the absence of batches of figures, was directly responsible for much preventable death and still more preventable misery throughout a whole generation. "What is most evident," *wrote an acute observer of social institutions*, "is not the difficulty of getting a fixed law, but of getting out of a fixed law; not of cementing (as upon a former occasion I phrased it) a cake of custom, but of breaking that cake of custom; not of making the first preservative habit, but of breaking through it, and reaching something better." The history of preventive medicine is a good comment upon that text. The bad statistics of the earliest apostles of sanitary and industrial reform injured their cause; the cake of customary indifference was not so easily broken. The good statistics of FARR and GREENHOW were the most powerful weapons in the hands of SIMON. When, full of years and honours, SIMON wrote his history of English sanitary institutions, the Nestor of preventive medical science did not forget what he owed to the labours of the statistician. FARR he happily characterised as "the man to bring into statistical relief, and to make intelligible and instructive to the common mind, whatever broad lessons were latent in the life-and-death ledgers of that great counting house." It was the General Register Office which "was rendering immense service to sanitary science by enabling it to use exact numerical standards in place of the former vague adjectives." The reforms needed in the "hungry *forties*" were great, the industrial transition of the early nineteenth century was painful. Had official vital statistics come into their own a generation sooner that history would have been different. Ignorance in a community, as in an individual, is far more cruel than malevolence. But the perils of our own time are still greater. One of these perils is the failure to realise the importance of a physical stock-taking, of learning the best and the worst about our nation. The machinery of a Census furnishes one item of this great account, an item which is essential to the interpretation of all others.

In combination with the returns of births, deaths, and marriages, the Census enumeration suffices for a reasonably complete evaluation of birth-, marriage-, and death-rates in all administrative areas and the chief occupational groups. Some difficulty has arisen in certain areas owing to the fact that the de jure population of a district may differ from the de facto population enumerated on Census day. This, it is believed, will be overcome on the present occasion. Again, satisfactory presentation of occupational mortality is very difficult to secure, and probably some of the difficulties are insuperable. But the arrangements made for this year's Census are the result of very careful consideration, and profit has been drawn from past and foreign experience; we have no doubt that the final analysis of industrial mortality will be even more illuminating than its famous predecessors. The Census machinery and the Registrar-General's returns cannot, however, provide two other items of the physical balance-sheet which are needed to complete the account. One is an appraisement of average physical fitness, the other a knowledge of morbidity-rates. The former is a subject to which the State has paid little heed save in times of war. It could only be dealt with by sampling, a method which is, statistically, quite satisfactory, provided the sample examined be a really random sample of the occupational or other class it is desired to study, and the limits of accuracy required have determined the size of samples. The method of physical examination appropriate to the case is still a matter of opinion; it must be simple yet accurate. *Professor* G. DREYER[1] *has brought forward evidence* to show that determination of the "vital capacity," advocated nearly 80 years ago by JOHN HUTCHINSON,[2] combined with two easily made measurements and the weight, suffice to characterise physical development. Professor DREYER'S plan is worthy of an extended trial. The incidence of sickness, not necessarily fatal sickness, is also a matter which can be more conveniently dealt with by the method of sampling than by any attempt at exhaustive enumeration. The possibility of such sampling furnished by the new system of medical records is one of the merits of a plan which has been the object of so much invective. Clearly of all these undertakings the Census enumeration is the most important. Given a Census, from data provided by the death returns alone, we can learn much; without a Census we can learn little indeed from mortality or morbidity records. There are very few duties of a citizen in time of peace which can be of *more importance than doing as much as in him* lies to make the enumeration complete and accurate.

◆

Alimentary Delay.

CURRENT usage has agreed upon time standards in regard to certain functions of the body. It is usual to retire to sleep at a particular hour and rise seven or eight hours later, to take our meals at intervals of five or six hours during the day, and to solicit an action of the bowels once or twice within 24 hours. Unfortunately, we have little to remind us of the time relation between the two latter events; generally speaking, the more quickly the food residues traverse the alimentary canal the more fluid and less formed are the excretions. But there may be a high degree of delay without our attention being called to it; residues arrive at the winning-post without word as to when they made the start. And at first no inconvenience may arise. As Sir W. ARBUTHNOT LANE reiterates in his Hunterian lecture, stasis which makes itself felt in adult life may have commenced early in the history of the individual; he suggests that it may even date from the epoch at which the napkin was discarded and the infant became habituated to a single daily action. As the skilled monthly nurse may achieve voluntary control for her charge before she leaves, this puts back the initiation of the sluggish habit to a very early date. LANE draws a picture of the later effects of this stasis so terrible that if even a tithe of it were realised we should adopt means of prevention rather than await the need for treatment. Dr. H. A. DES VŒUX, in our correspondence columns this week, reminds us with what mischievous carefulness all the laxative properties of a natural diet are kept away from the well-to-do child. Potato parings, apple peel, and cabbage stalk are eliminated and *enough milk often given to supply in itself* all nutritive requirements, leaving little or no stimulus to peristalsis. Close rooms and confined limbs often enough still further limit the healthy metabolism. And soon a slippery insoluble liquid has to be added to the diet from which the natural residue has been removed. Last and worst, recourse is had to castor oil, that toothsome dainty which was so providentially diverted to munitions a while ago. The diet of slugs and snails and puppy dogs' tails, suggested by the nursery rhymester for little boys, was harshly expressed, but physiologically it was righteous compared with the complementary diet of sugar and spice and all that's nice, and far less calculated to give rise to stasis. The correct principles of alimentary training in young children are simple enough, and are only difficult because they encounter ignorance and prejudice.

FEES FOR PUBLIC VACCINATION.

THE Association of Public Vaccinators of England and Wales has approached by circular members of boards of guardians throughout England and Wales in the matter of the fees payable for public vaccination, pointing out that the minimum fees for domiciliary vaccination are at present precisely the same as they were from 1899 to 1907. The Association appeals to the guardians for an increase in the remuneration of the public vaccinator, both in view of the general increase in cost of living and diminished value of money, and more particularly because of the largely increased expense in every department of medical practice, particularly in the important matters of travelling and dressings. The Association states that from 1907 to 1919 there was a reduction in the minimum fees; this change was made in face of the strongest protest and, it considers, left a deep sense of injustice on the mind of the public vaccinator. Certainly it was at variance with the recommendation of the Departmental Committee appointed by the Local Government Board, which, after a most exhaustive and searching inquiry, expressed the opinion that there should be no change in the minimum unless and until the public vaccinator should be given the status of an officer of the guardians, eligible for superannuation and with fixity of tenure. This recommendation was not adopted. The public vaccinators feel that the Ministry of Health, in the Order of last year, while removing a grievance for which the Association had been attempting to obtain redress for many years before the war, left to the boards of guardians themselves the opportunity of making such increases upon the minimum as would be justified by reasonable consideration of the altered circumstances created by the war. The Association is confident that boards of guardians only need this matter to be brought before them to recognise the necessity for such an increase of the existing fees, either by revision of contract or by percentage bonus additions to fees, as may meet the increasing difficulties *of the public vaccinator, and assimilate* his position to that of other branches of the public service. We need hardly say that the views of the Association will be endorsed by the medical profession. Should a recent testimonial be required to the work of the public vaccinator, it is given by the Chicago Department of Health, always to the fore in sanitary instruction, which prints in its last bulletin a "vaccination creed" based upon many years of practical experience in public vaccination. From 1899 to 1920 inclusive 5565 cases of small-pox occurred in Chicago with 577 deaths. Of the 448 vaccinated persons who took small-pox none died. No revaccinated person took small-pox.

Annotations.

"Ne quid nimis."

VITAL STATISTICS FOR 1920.

WE have received from the Registrar-General the following provisional figures for the birth-rate, death-rate, and infant mortality in England and Wales during the year 1920:—

—	Birth-rate per 1000 total population.	Death-rate per 1000 population.	Deaths under 1 year per 1000 births.
England and Wales	25·4	12·4	80
96 great towns, including London	26·2	12·5	85
148 smaller towns	24·9	11·3	80
London	26·3	12·4	75

In the great towns are included all those with a population exceeding 50,000 at the Census of 1911; the smaller towns are those with 20,000 to 50,000 inhabitants. The death-rate for England and Wales relates to the whole population, but that for London and the groups of towns to the civilian population only.

Although the rates here shown are provisional, no subsequent adjustment will affect the following important conclusions—namely: (1) that the birth-rate for 1920 is the highest of the decade; (2) that the death-rate is the lowest ever recorded; (3) that the infant mortality is the lowest ever recorded; (4) that the number of births is the highest ever recorded; (5) that the number of deaths is the lowest recorded since 1862, when the population was only 20 millions.

A NEW SPIROCHÆTAL DISEASE IN JAPAN.

SOME of the same Japanese investigators who, early in 1915, discovered the virus of spirochætal jaundice (Weil's disease, Spirochætosis ictero-hæmorrhagica), now give[1] the successful results of an inquiry into the ætiology of a somewhat similar disease, prevalent in various country districts of Japan, but not found in the towns. This disease is known in the province of Fukuoka, where the work was carried out, as nanukayami (seven-day fever). It has, however, been fully identified as occurring in at least eight other provinces under a variety of local names. The disease is confined absolutely to country districts, which made its laboratory investigation extremely difficult. Clinically, it is described as a fever setting in suddenly, with great depression, pains in the muscles, injection of the conjunctivæ, intestinal disturbances, and swelling of lymphatic glands. In the early stage there is albuminuria, and leucocytosis is also a feature. The course is comparatively short—round about seven days—and the mortality is fortunately nil. Neither jaundice nor hæmorrhages from mucous membranes are met with. It is interesting to note that as far back as 1889, in Japan, atypical cases of Weil's disease were recognised during epidemic periods, in which jaundice did not occur. This observation was fully confirmed on the Western Front during the war. For a long time *nanukayami* was believed to be simply atypical Weil's disease, without jaundice, and it was only in 1910 that Inada, after a careful epidemiological and clinical study, suggested strongly that seven-day fever was a separate clinical entity. The brilliant results of the investigation of Weil's disease, resulting in the discovery of the causal spirochæte, suggested at once a similar line of experiment in connexion with nanukayami. The cause of this fever has now also been found to be a spirochæte, to which the name *Spirochæta hebdomadis* has been given. The writers state that it is identical morphologically with the *Spirochæta ictero-hæmorrhagiæ*, but is clearly differentiated from it by immunity reactions. The experiments bearing on this latter point are given in complete detail, and appear quite sound. The *Spirochæta hebdomadis* is found by inoculating guinea-pigs intraperitoneally with blood from cases of the acute disease. It brings about death in 60 per cent. of the animals, while the remainder gradually recover from the infection. An unbiassed reader of the work cannot help being struck with the exact similarity of the temperature charts of guinea-pigs fatally infected with nanukayami, and those inoculated with blood from a case of Weil's disease. There is high fever lasting for four to five days, followed by sudden collapse before death. Moreover, the authors state that, in 17 per cent. of the animals infected with nanukayami, jaundice occurs. Spirochætes are found abundantly in the liver of the infected animal. Thus, apart from the serological distinctions, the *Spirochæta hebdomadis* and *Spirochæta ictero-hæmorrhagiæ* would appear from their main effects to be very closely allied species.

---

[1] Ido, Y., Ito, H., Wani, H., Okuda, K., and Hoki, R.: Mitteilung ueber die Aetiologie, Epidemiologie, und Pathologie der "Nanukayami" (Siebentagefieber). Ido, Y., Ito, H., and Wani, H.: Die zweite Mitteilung ueber die Aetiologie der Nanukayami (Siebentagefieber). (Mitteilungen aus der Mediz. Facultät der Kaiserlich. Universität Kyushu, Fukuoka, Japan, Band. v., Heft. iii., 1920, ss. 81-130.)

The main point of interest really centres round the carriers of the two spirochætes. The brown rat, *Mus decumanus*, has been clearly proved to be the chief carrier of *Sp. ictero-hæmorrhagiæ*, and spirochætal jaundice is a disease found in towns and in places where men are congregated together. On the other hand, nanukayami is a disease of country districts only, and its carrier has been clearly identified by the present investigators as the Japanese field-mouse (*Microtus montebelli*). The urine of this animal, just as in the case of the rat, appears to be the main source of infection. It seems possible that the two spirochætes of nanukayami and Weil's disease are really the same, modified by their development in the different animals which act as their intermediate host. It is quite obvious that, at any rate, they are closely related to one another.

The Japanese writers are to be congratulated both on discovering the cause of a fever of hitherto unknown origin, and on pointing out the field-mouse as a carrier of disease. Their work suggests that many of the short fevers, prevalent locally in different parts of the tropics, might well be elucidated on similar lines. Although the Japanese authors, who write in the German language, refer to the disease under the name Siebentagefieber (seven-day fever), the condition must, of course, not be confused with the fever known to us as trench fever, and in German literature often named Fünftagefieber (five-day fever).

HEALTH REFORM IN IRELAND.

A Dublin correspondent writes:—The Chief Secretary has notified the Irish Public Health Council that it is not the intention of the Government to undertake legislation along the lines of the Council's report, because of the expense that would be involved. At his interview with the Council in September, Sir Hamar Greenwood had declared that on the ground of expenditure nothing would stand in the way of the Government undertaking legislation, but that the moment was inopportune from a political point of view. Those interested in medical reform will make their interpretation of the Chief Secretary's statements. The net result of health legislation in the United Kingdom of Great Britain and Ireland in the past two years is that England and Scotland are each provided with a full working Ministry of Health, while Ireland—where health reform is even more pressing—is left with an Advisory Council whose advice is treated with contempt by the Government. The late Chief Secretary, Mr. MacPherson, had pledged himself to legislate on lines the Council would propose, and at his request, and in reliance on this pledge, the Council drafted a thorough-going and careful scheme of reform. But Mr. MacPherson did not stay long enough in Ireland to redeem his pledge, and apparently it bound no one else.

THE UNCINARIASIS COMMISSION OF THE ORIENT.

AMONG the many large and praiseworthy activities of the Rockefeller Foundation International Health Board is its world-wide campaign against hookworm infection. In 1914 the General Director of the International Board visited a number of countries in the Near and Far East, including Egypt, Ceylon, the Philippine Islands, and the Federated Malay States, making preliminary surveys and collecting information to facilitate the studies of the experts who might eventually make detailed investigations in these countries. In 1915 a Commission was appointed the expenses of which were defrayed by the Rockefeller Foundation; it comprised three members, Drs. S. T. Darling, M. A. Barber, and H. P. Hacker, all of whose names are already well known to students of tropical medicine in connexion with scientific work in the Panama Canal Zone and elsewhere. The Commission became known later as "The Uncinariasis Commission of the Orient," and its labours were mostly carried out in the Federated Malay States, Java, and the Fiji Islands. The terms of reference were "to determine to what degree uncinaria infection is a menace to the health and working efficiency of the people of a country," and plenty of evidence was found that ankylostomiasis caused much ill-health and that it led to considerable inability to work. The intimate relation that was discovered to exist between malaria and hookworm disease as disabling factors rendered it necessary that the Commission should devote almost as much time to the local study of malaria as to hookworm disease, in order to determine the relative importance of the two infections as causes of anæmia.

In the abridged edition of the Commission's report[1] now published, it is stated that on the whole in Malaya, where malaria and ankylostomiasis are common, severe anæmia due to the latter is less frequent than severe anæmia due to the former. As regards the relation between the species of worm and the degree of anæmia, the Commission observed that in cases of infection the same number of worms caused a greater degree of anæmia among Chinese subjects than among Tamils. As the Chinese harbour much larger numbers of *Ankylostoma duodenale* than do the native Indians, the fact was taken to indicate that the latter species of worm is probably a more powerful agent in the causation of anæmia than *Necator americanus*. Considerable attention was given by the Commission to the investigation of the value of various drugs in the treatment of hookworm disease. Native patients, however, were found sometimes to be difficult of control, and valuable observations were rendered useless by the patients absconding during the period in which the effects of remedies were being watched. Some of the experiments, however, were made in jails and hospitals where better control was possible. Various vermifuges were tried and attempts were made to reach a scientific conclusion as to the relative merits and efficacy of differently graduated doses of chenopodium and thymol for the routine treatment of uncinariasis. Ultimately it was proved that chenopodium in small doses was more efficacious than similar doses of thymol; chenopodium also showed a satisfactory efficacy in a greater range of doses. While, dose for dose, both drugs exhibited about equal efficacy in removing *Necator americanus*, chenopodium was superior to thymol in removing ankylostomes, the more resistant species of hookworm. It appears also that chenopodium is more effective in removing other parasitic worms such as ascaris and trichuris. The valuable work done by the International Health Board of the Rockefeller Foundation, in its campaign against hookworm disease, deserves the warmest recognition of all who are interested in the economic development of those countries in Asia and elsewhere that have been kept back by this disabling disease.

THE GROWTH AND SHEDDING OF THE ANTLER.

A DISTINGUISHED surgeon has followed up his work on growth of bone by a study of the growth and shedding of the antler,[1] of the histological phenomena observed during these processes and their relation to the growth of bone. On the authority of Sir William Flower the statement is made that in the larger species (such as the Irish elk) the weight of the antlers is more than that of all the bones of the skeleton put together. This is not the most remarkable fact about the deciduous antlers of the deer. Not only does enormous growth, "according to plan," of these weighty defensive organs occur within three or four months, but the skin or velvet which covers these often palmate outgrowths, grows pari passu with the bone itself, so that there is complete reproduction of the whole of the cutaneous tissues, epithelium, cutis, gland and hairs, blood-vessels, lymphatics, and nerves with each renewal of the antlers. Obviously to do this the vessels of the velvet must grow with great rapidity to supply the abundant pabulum necessary for the skin growth, for these vessels have but few connexions with the special set of blood-vessels which supply the rapidly growing bone. The nerves to protect the sensitive growing antlers are outgrowths from the trigeminal nerve. The bony part of the antler is derived from a pedicle projecting from the frontal bone. The rapidity of growth is so great that all phases of bone development by osteoblasts can be found occurring simultaneously in one part or other of a half-grown antler, and the phenomena are, in the main, analogous to those of the growth of bone in other parts of the mammalian skeleton. Even from its earliest growth arrangements are made for the rapid shedding of the antler after it has performed its evanescent purpose. Osteoblasts form ossein which ultimately constricts the internal blood-vessels supplying the growing bone, leading to ischæmic necrosis, and the antler is ultimately shed from the action of the living tissue on the proximal side in the pedicle. Similar arrangements are also made for the shedding of the velvet. At first the larger cutaneous blood-vessels lie in grooves in the antler, but ultimately the excessive growth of bone forming the corona encroaches on them and subsequently obliterates them. The osteoblasts are evolved from pre-existing bone cells or osteoblasts in the pedicle, and Sir William Macewen thinks that the mass production of bone depends not only on normal cell division of the osteoblasts, but is aided by nuclear budding which he has studied and figured. A new and larger antler grows yearly from a single small centre of ossification in the frontal bone, forming a pedicle identical in structure with frontal bone and covered at the beginning of the growing period with cartilage which ossifies from the base upwards. The cartilage grows in advance until the full size of the antler is reached, when its ossification becomes complete. The pedicle once formed is a permanent structure, growing in circumference during subsequent years. The antler first appears during the second year of the animal's life, when it presents only a single stem. Injury or disease of the pedicle or skull makes corresponding modifications in the growth of the antler. The separation of the antler is primarily due to the withdrawal of its blood-supply, both of the bone and velvet. Obliteration of the superficial vessels in the cutis-velvet takes place at the corona, the edge of the corona presses on and through the cutis, and, as there is no collateral supply from the bone vessels, the whole velvet covering becomes avascular, dries, shrivels, and peels off in shreds, although the growth in the interior of the antler is still active. The separation of the antler from the pedicle is effected also at the level of the corona, the bone gradually becoming avascular, very dense, with complete obliteration of the relatively thin-walled vessels. At the line of separation or shedding the pedicle becomes very vascular and a "granulation tissue" forms and gradually loosens the organic connexions between the pedicle and the dead antler, while at the same time the deeper bone cells of the skull and pedicle proliferate, assume the rôle of osteoblasts, and are ready for fresh effort in producing a new antler. The whole process of shedding of the antler takes place in the open air and aseptically. No mention is made of osteoclasts as agents in the process. Sir William Macewen refers only briefly to the effects of castration on antler growth, and suggests further inquiry in this direction. Nature's methods of self-amputation, be it by way of autotomy, shedding of an antler, or fall of a leaf, are scientifically perfect and are prototypes of aseptic surgery in its most complete and successful application.

THE INSTITUTE OF PHYSICS.

THE first move towards a closer relation between workers in physical science dates from March, 1918, when, under the presidency of Professor C. H. Lees, representatives of four societies met to define the lines of future coöperation. These were the Faraday Society, the Optical Society, the Physical Society of London, and the Rontgen Society. Their decision to form an Institute of Physics analogous to the existing Institute of Chemistry took effect, and the Institute was duly incorporated last November. The Royal Microscopical Society has now joined the Institute, and it is anticipated that other societies will follow. A circular has been issued reciting the objects of the Institute and the regulations proposed for the admission of Members, Students, Associates, and Fellows. The two latter groups will use the title A.Inst.P. and F.Inst.P. respectively. The regulations for admission and for professional conduct are based upon those ruling in the sister Institute, and they will doubtless aid in raising the status of the physicist in the public mind alongside of the chemist. All branches of physics are in reality closely inter-related, and nothing but good can come of the amalgamation.

TUBERCULOSIS OF THE LIP

Dr. Erwin P. Zeisler,[1] dermatologist to the Cook County Hospital, Chicago, records an example of this rare condition in a man, aged 56, who sought advice for a painful swelling of the lower lip, which had appeared ten months previously. The entire lower lip was uniformly enlarged and indurated with several small areas of denuded epidermis. The inner aspect of the lower lip down to the gingival border showed a superficially ulcerated area, about 2 cm. broad, surrounded by œdematous mucous membrane. On palpation the ulcer felt moderately indurated. An ulcer was also found on the inner aspect of the upper lip and a third ulcer opposite the last lower right molar. In view of the patient's age, the induration, and the presence of a hard mass of glands in the submental region, most of the members of the Chicago Dermatological Society, where he was exhibited, expressed the opinion that the lesion on the lower lip was an epithelioma. The presence of the other ulcers, however, was not consistent with this view, and the diagnosis of tuberculosis of the lip was established by finding large numbers of acid-fast bacilli, morphologically identical with tubercle bacilli, in smears and scrapings from the mouth, as well as by the results of a biopsy which showed isolated and conglomerate tubercles with characteristic arrangement of giant cells, epithelioid cells, and small round cells. A few tubercle bacilli were found in the corium. Examination of the chest showed chronic pulmonary tuberculosis of the fibroid type. A general tuberculosis regimen was instituted, cocaine was applied to the lip to relieve the pain, the ulcers in the mouth were swabbed daily with diluted hydrogen peroxide, and filtered Coolidge treatment was administered over the lip and submental region, with the result that considerable improvement took place before the patient disappeared from observation.

THE CENTRAL MIDWIVES BOARD.

FROM the recent report on the work of the Board for the year ended March 31st, 1920, we learn that on that date the Midwives Roll contained the names of 45,960 women, a net increase for the year of 1794. Of these, the trained midwives number 37,056 and the untrained 8904, the proportions being 80·6 and 19·4 per cent. But, as we have frequently pointed out, the percentage of trained midwives who practise as such is relatively small, amounting only to 21·5 of the trained women on the Roll. Of the untrained, approximately 40·7 per cent. are in practice, though frequently to a small extent only. The actual total number of practising midwives has been ascertained to be about 11,500. There are 159 institutions and homes in England and Wales at which midwives may be trained, of which 63 are Poor-law institutions. 104 registered medical practitioners are approved by the Board as lecturers, and 49 practising midwives as teachers, responsible for the practical training. Private training accounts for the entry on the Roll of 1107 midwives practising in 1919, or 9·6 per cent. of all practising midwives. Of 2344 candidates who completed their examination 1904 passed, the percentage of failure being 18·8 and varying widely over the country. Manchester's failures amounted to 34 per cent., Leeds's but to 13 per cent. Of the 1904 successful candidates 1238, or 65 per cent., declared their intention of practising as midwives, and of this number 642, or 51·9 per cent. intended to practise in rural districts, where at the present time the shortage is most keenly felt. During the year 54 midwives were dealt with by the Board under its penal powers. They had to answer charges of malpractice, negligence, or misconduct, resulting in the immediate removal from the Roll of 35 names. Two other women were censured and two cautioned, while in four cases no action was taken. 105 women surrendered their certificates on the ground of old age, ill-health, or inability to comply with the rules. During the year the Board discussed the possibility of limiting the number of cases to be taken by midwives. A local supervising authority had represented that in many cases omissions and failures on the part of midwives to observe the rules were attributable to the fact that they had undertaken more confinement cases than could be coped with. The Board decided that it was impossible to rule that a midwife should not take more than a certain number of cases in the course of a year, as the number of cases which could be taken without affecting the proper conduct thereof depended on factors of a varying nature, such as concentration and dispersal of cases, the normality or otherwise of the cases, the powers of endurance of the midwife, and the like. Compliance with the rules as they stand should prevent scamping of work.

RECENT WORK IN HOLLAND ON REFLEXES.

THE efforts of the Anglo-Batavian Society have been successful in ensuring interchange of medical thought between this country and Holland, a matter of importance in view of the serious barrier set up on each side of the short sea passage by unfamiliarity with the language. Very few Dutch monographs are accessible to English readers, therefore we welcome with particular pleasure Professor Murk Jansen's study of dysostosis, as it appears in his book on "Feebleness of Growth and Congenital Dwarfism."[1] The first lecture of a series by distinguished Dutch medical men was delivered before the Royal Society of Medicine on Jan. 17th, by Dr. J. K. A. Wertheim Salomonson, professor of neurology in the University of Amsterdam, who took for his subject "Tonus and Reflex." Research into the electrical response of muscle tissue has been especially brisk in Holland, probably owing to the fact that it was another Leyden professor, Dr. W. Einthoven, who invented the string galvanometer which widened so greatly the field of this research. Professor Salomonson began his lecture by classifying muscle contractions into groups according as they are or are not accompanied by demonstrable electric currents of action. Simple muscle twitches, always preceded by a double-phased action current, are typically found in deep reflexes, whether tendon or periosteal, and in the muscle clonus resulting from lesion of the lateral tracts in the spinal cord. Irregular alternating current with some 50 periods a second is characteristic of tetanic contraction, and is met with in every voluntary movement. Passive movement of a limb causes no oscillation of the galvanometer, and in myelitis with complete paralysis of the lower limbs enormous involuntary muscle spasms may occur without any action current being produced. Professor Salomonson went through a whole series of maladies affecting muscular tone, showing the changes in the electrical reactions and the lessons to be drawn from these changes. The lecture, with many explanatory diagrams, is to appear in an early issue of *Brain;* we are content merely to cite here one deduction of great interest which has resulted from these investigations. It is common knowledge that in lateral sclerosis the Babinski reflex reverts to the extensor type, which is normal in young children. The centrifugal impulses for the plantar reflex passing down the pyramidal tract being cut off, and the cerebral centrum thus put out of action, the spinal centrum for the extension of the hallux, which was an important one in the history of the race, reasserts itself, and is further heightened by the increased secondary tonus reflex of the cord, now no longer controlled by a higher centre. We felicitate Professor Salomonson on his contribution to exact medicine, and the Anglo-Batavian Society on its enterprise.

THE HOUSING PROBLEM IN PARIS.

AT its last sitting, before the New Year adjournment, the Paris Municipal Council adopted a housing scheme. Mons. Etevenon, municipal inspector of houses, described the project, for which 14,000 metres of land have been secured in the Picpus quarter. There will be three streets with houses six storeys high, but the houses will be so placed and the space around so spacious that all the walls will be exposed daily to direct rays of sunlight. They will contain 628 tenements and there will be a large central square or playground. Of these 300 will consist of a kitchen and three or four rooms and 200 of a kitchen and two rooms. Each room will measure from 11 to 13 square metres. Then there will be 100 cabinets where the tenants can take douches and a steam laundry will be put at their disposition large enough for 80 tenants to do their washing at one and the same time. They will save much time and trouble by using the machinery available; and, though a small charge will be made, this will cost much less than if each tenant had to warm his own boiler and work his own mangle. The sum paid will help to defray the general cost. In the same way also shops and trading premises on a level with the streets will be let at commercial rents, to reduce the deficit which may result if, as proposed, the tenements are let at a low rental. The capital expenditure voted for this enterprise is 27 million francs, or at the normal rate of change £1,080,000; but as it will take three years to build these three new streets it is calculated that the cost will be much less towards the end than at the beginning of this period. In any case, the municipality feel they must strive to solve the housing problem, even if this involve financial loss. Besides, 628 good tenements, though involving a loss at first, will prove in the long run a profitable property. This is all the more probable as few tenements will offer such advantages. Nor is this the only enterprise of the sort the city of Paris has in hand, though it is the newest venture. Eleven groups of cheap buildings commenced before, and interrupted by, the war are now being completed. Buildings commenced by private enterprise, but abandoned, have been bought up by the municipality, and thus in a few months' time the city will be able to offer at cheap rentals some 8000 tenements to the distressed population. A great deal also has been done within a radius of 30 miles outside the capital to meet the lack of housing accommodation.

---

THE U.S. ARMY MEDICAL SERVICE.

PROBLEMS of reconstruction have had much attention in the United States during this year, perhaps in part because she has had fewer immediate anxieties than other nations; certainly they have been approached with great breadth of view. The latest evidence to come before us concerns the Army Medical Service, dealt with in a paper by Major F. Kramer, Medical Corps, U.S. Army, in the *Military Surgeon* for December. It has been decided that there shall be established at Washington, D.C., the Army Medical Centre. For it there has been reserved a site of great natural beauty, a well-situated large natural amphitheatre. Here will be built the large single building of the Army Medical School, where will be centred post-graduate instruction for all divisions of the Medical Department, including, be it observed, the Dental and Veterinary Corps, with complete laboratories for research work. Associated with this will be built a new hospital, the Walter Reed General Hospital of 750 beds. There will be houses for officers and men, and recreation grounds. The Surgeon-General's library and museum will be here, and the whole is expected to become an important unit in the post-graduate instruction of the country generally, and a common meeting place for all in the medical profession within and without the service. Meanwhile the education of officers is not being neglected, and 20 medical officers are at present seconded and undergoing special courses in civil medical schools. A new portal of entry has been opened to the service from the civil profession, for the best schools may recommend honour students, who are physically fit, to be house surgeons or house physicians in military hospitals for a year, after which, if approved, they are commissioned as first lieutenants. Orderlies, too, are being better trained, especially in work in laboratories and operating theatres, extra pay being given when qualification is shown. The pay of the Nurses has been raised 20 per cent., and they have been given relative rank. A new Army Medical Nursing School and Nurses Home will be part of the centre. Here army nurses will get a three years' training. This aims to be an ideal nursing school, to turn out a better trained body of nurses, and to maintain full and cordial relations with the profession at large.

PROFESSIONAL CONDUCT AND ERASURE FROM THE REGISTER.

THE periodical statement from the General Medical Council summarising the resolutions and decisions of the Council upon forms of professional misconduct which have from time to time been brought before them, in the exercise of their disciplinary jurisdiction over the members of the medical and dental professions, has just been issued. This jurisdiction was conferred upon the Council by the 29th Section of the Medical Act, 1858, and by the 13th Section of the Dentists Act, 1878. A few instances of professional misconduct are set forth, not as constituting a complete list of offences which may be punished by erasure from the Register, but as broad examples. The instances thus brought to the notice of registered medical and dental practitioners may briefly be described as follows:—

(1) *Certificates, notices, reports, &c.*—The signing and giving in a professional capacity of any certificate or document of a kindred character, for subsequent use in courts of justice or for administrative purposes, which is untrue, misleading, or improper. Such documents include certificates, notifications, reports, &c., under the statutes and Acts relating to births, deaths, and disposal of the dead; lunacy and mental deficiency; vaccination; factories; education; public health; workmen's compensation; notification of infectious diseases; national insurance; old-age pensions; merchant shipping; sick benefit, insurance, and Friendly Societies; the procuring of Foreign Office passports; the excusing of attendance in courts of law, in the public services, in public offices, or in ordinary employment; and in connexion with naval and military matters.

(2) *Unqualified assistants and covering.*—The employment in connexion with professional practice of an assistant who is not duly qualified and registered, or the enabling of any person, known to be unqualified and unregistered, to attend or treat a patient in respect of a matter requiring professional discretion or skill. (These rulings do not apply so as to restrict the proper training and instruction of bona fide students, or the legitimate employment of dressers, midwives, dispensers, surgery attendants, and skilled mechanics under the immediate personal supervision of a registered practitioner.)

(3) *Sale of poisons.*—The employment for his own profit and under cover of his own qualifications, by any registered practitioner who keeps a shop or other place in which scheduled poisons or preparations containing scheduled poisons are sold to the public, of assistants who are left in charge, but are not legally qualified to sell scheduled poisons.

(4) *Association with unqualified persons.*—Any assistance given, either by administration of anæsthetics or otherwise, to an unqualified person attending or treating any other person in respect of matters requiring professional discretion or skill.

(5) *Advertising and canvassing.*—The practices of (*a*) advertising by a registered medical practitioner with a view to his own gain, particularly if depreciatory of other practitioners, or of sanctioning such advertising; (*b*) employing or sanctioning employment of agents or canvassers for the purpose of procuring patients; and (*c*) associating with or accepting employment under any association which practises canvassing or advertising for the purpose of procuring patients.

(6) *Association with uncertified women practising as midwives.*—Knowingly enabling uncertified women, on pretence that such women are acting under direction, to attend women in childbirth, contrary to law. It is provided in the Midwives Act, 1902, and in the Midwives (Scotland) Act, 1915, that "no woman shall habitually and for gain attend women in childbirth otherwise than under the direction of a qualified medical practitioner, unless she be certified under this Act."

A registered practitioner who is proved to have committed any of the offences detailed above is liable to have his name erased from the Medical Register, and it is well that categorical warning should come periodically from the Council. It is clear that under several of the headings a practitioner through ignorance, coupled with carelessness, may be placed in a seriously unethical position.

THE REPORTING OF FOOD POISONING.

UNDER existing regulations neither medical practitioners nor the general public are obliged to report cases of food poisoning to the medical officer of health, but there is every hygienic and social obligation for doing so. A statutory duty rests upon medical officers of health to report to the Ministry of Health any outbreak of serious epidemic disease, and in a recent circular (Memo. 39, Foods) the Ministry requests medical officers, whenever they have reason to suspect that any death or outbreak of illness in their districts is due to food poisoning, promptly to notify the Ministry, which may be in a position to offer useful assistance in regard to the immediate measures to be taken, and to elucidate points at present obscure in the causation of food poisoning. Early notification may show that other cases are occurring elsewhere from similar causes—e.g., where one or two members of a household are suffering in consequence of the consumption of canned food from a particular tin other canned foods of similar origin may be causing illness elsewhere. In any outbreak where the implicated food has been prepared in the district the medical officer is advised to proceed at once with detailed investigations into the conditions of its preparation, and to obtain material for bacteriological or chemical examination, steps being taken the while to prevent further consumption of the suspected food by stopping its sale and recovering unconsumed portions of what has already been sold. Suggestions are made in the circular for the collection and examination of material for chemical and bacteriological examination, and the reminder is added that the serological reaction of the blood of persons attacked should always be bacteriologically investigated. An appendix to the memorandum contains the headings of inquiries appropriate for outbreaks of poisoning by meat foods and when contamination with inorganic poison is suspected.

THE PRESCRIBING AND DISPENSING OF IODINE IN LARGE DOSES.

WRITING in THE LANCET last year Mr. Tom Bird[1] drew attention to the success which Dr. Louis Bourdreau has met with for many years in the treatment of cases of tuberculosis with large doses of iodine. Mr. Bird, using iodine in similar dosage, has obtained very good results in many cases of arthritis. Commencing with 1 gr., the dose is increased to about 3 gr. thrice daily, the latter amount being equivalent to 36 minims of the tincture of iodine of the French Codex. No inconvenience was caused beyond slight nasal catarrh, and it is apparently suggested that the absence of potassium iodide in the French tincture may have contributed to this freedom from iodism. In this connexion we may remark that symptoms of iodism following the repeated administration of iodine are not unknown; iodism from this cause is undoubtedly rarer than from the ingestion of iodides, but, of course, the latter are much more frequently used. In a paper recently read before the North British Branch of the Pharmaceutical Society[2] it is stated that since the appearance of Mr. Bird's article these large doses of iodine have been frequently ordered, and some prescribing and dispensing difficulties have arisen in this connexion, partly through unfamiliarity with the solubilities of iodine on the part of prescribers. The French tincture may be ordered, but this is not convenient for dispensers, particularly as the preparation is made up with 95 per cent. alcohol, which is not official in this country and must be prepared by adding absolute alcohol to rectified spirit. It is suggested that each grain of iodine may be suitably dissolved in a mixture of 3 minims of ether and 9 of rectified spirit, or in 12 minims of rectified spirit if ¼ gr. of potassium iodide be added, a quantity which can hardly be considered objectionable. The strong tincture of iodine of the B.P. contains 1 gr. of iodine and ⅗ gr. of potassium iodide in 11 minims. According to the solubilities given, another convenient method would be to order each grain of iodine to be dissolved in 16 minims of rectified spirit. It seems that in Scotland, at any rate, a given number of drops of tincture is usually directed to be taken in water. The drop is, of course, a variable quantity; it is stated that 15 drops of the French tincture measure 10 minims, and that if this amount is added to less than about 5 ounces of water free iodine separates as a film on the surface. Such papers as the one quoted are to be welcomed as likely to clear up misunderstanding between prescriber and dispenser.

PUERPERAL AUTO-INFECTION.

ATTENTION has been drawn to the dangers of meddlesome midwifery more than once in the columns of THE LANCET. This danger is not to be considered less, but rather it is emphasised, by the discovery that pathogenic streptococci exist in the cervix and posterior cul-de-sac of the vagina before, during, and after parturition in women who have not been examined. At the same time, the results of bacteriological findings by Dr. G. Rustra, reported in the *Philippine Journal of Science* (1920, xvii., 119), seem to prove definitely that cases of auto-infection do occur in the puerperium. Eighty women were examined bacteriologically both ante-partum and post-partum, and the results classified according to the site at which bacteria were found, and whether these were hæmolytic streptococci, non-hæmolytic streptococci, or other bacteria. Only 9 of the 80 cases were sterile ante-partum and only 3 were sterile post-partum. *Streptococcus pyogenes* was found in 11 ante-partum cases; these caused infection in 4 cases, the streptococcus being twice recovered in pure culture and twice in association with *Staphylococcus aureus*. Of 3 cases with non-hæmolytic streptococci ante-partum, 1 suffered from fever in the puerperium. The author does not describe what precautions were taken to avoid contamination during the bacterial examinations, and in view of the varying results obtained by investigators using different methods this is a serious omission. The question is one upon which there is even now a great deal of difference of opinion. The majority of obstetricians believe, and clinical evidence appears to support their belief, that the vagina of a healthy woman does not contain pathogenic organisms and that auto-infection is very rare, if, indeed, it occurs at all. On the other hand, in a number of cases organisms have been found in the vagina of the pregnant woman, and these have been described as being of a pathogenic character and capable of causing puerperal septicæmia. If Dr. Rustra's observations are confirmed, and if his methods are such as to preclude all possibility of contamination, these results will tend to support the view that auto-infection is possible and probably not infrequent. At the present time, however, the available evidence, both clinical and bacteriological, points the other way.

MATERNITY AND CHILD WELFARE IN INDIA.

THE valiant struggle of the Women's Medical Service of India against prejudice, dirt, and ignorance does not cease, and new methods are constantly being devised to popularise the health movement among Indian families. The annual report for 1919 of the National Association for Supplying Female Medical Aid to the Women of India records an increased Government subsidy of 2¼ lakhs (over £20,000). It is also recorded that all hospitals under members of the Women's Medical Service now have qualified matrons and are engaged in the training of Indian and Anglo-Indian nurses and midwives. The Council note the revival of activity in the attempt to improve conditions of childbirth, and emphasise *the need for the training, followed by constant* supervision, of the indigenous dai (hereditary midwife). The women of the poorer classes turn to the dai, even as in England they used to cling to the handy woman, and experience has shown that more useful work can be done at present by educating the dai than by attempting to supplant her. The Victoria Memorial Scholarships Fund has decided to assist only indigenous dais to become trained midwives, since the few better-educated women who desire training have other opportunities for obtaining assistance. Unfortunately the trained dai who works among those sections of the community tenacious of old customs tends to revert to former practices unless constantly supervised. An Association for the Provision of Health and Maternity Supervisors has been formed, but the difficulty of selecting candidates suitable to be trained for these higher posts is great. The standard of obstetrical knowledge required even of doctors, men and women, trained in India will also have to be raised if maternity conditions are to be improved. At present the universities require the candidate for a degree in midwifery to have conducted no more than six cases. On the other hand, Dr. D. Curjel, recently appointed medical secretary to the Victoria Memorial Scholarships Fund, records that interest and enthusiasm for child welfare schemes is becoming noticeable throughout the country. A further indication of this interest is the success of the Maternity and Child Welfare Exhibition held at Delhi in February last. A sumptuous volume,[1] excellently printed and illustrated, describes the various sections of this exhibition, and not only includes the leaflets and pamphlets issued, but reprints the lectures delivered. Among the medical lecturers were Dr. A. Lankester, Dr. Ruth Young, Lieutenant-Colonel A. Frost, R.A.M.C., Major F. Cragg, I.M.S., and Dr. Yamini Sen. The need for attention to child welfare in India could not be emphasised more strongly than in the results of two inquiries quoted by Dr. Lankester. The total number of pregnancies in a series of 50 married women who presented themselves at the Lady Dufferin Hospital at Karachi was 241. The number of children surviving was 20. In Delhi, of 1000 consecutive multiparæ attended in labour, 657 had lost their first-born.

[1] This report may be obtained on application (accompanied by 4 annas) to the honorary secretary, the Lady Chelmsford All India League for Maternity and Child Welfare, Viceregal Lodge, Delhi. This and the other reports referred to are published by the Superintendent, Government Printing, 8, Hastings-street, Calcutta, India.

A POST-GRADUATE SCHEME FOR LONDON.

THE Minister of Health, with the concurrence of the University Grants Committee, has appointed a Committee with the following terms of reference:—

> "To investigate the needs of medical practitioners and other graduates for further education in medicine in London, and to submit proposals for a practicable scheme for meeting them."

The Earl of Athlone (chairman of the Governors of Middlesex Hospital) will act as chairman, and the following constitute the committee: Dr. H. J. Cardale; Sir Wilmot Herringham, M.D.; Sir George Makins, F.R.C.S.; Sir George Newman, M.D.; Sir Robert Newman, M.P.; Sir Edward Penton; Sir E. Cooper Perry, M.D.; Mr. J. Dill Russell, F.R.C.S.; and Dr. T. W. Shore. Mr. A. L. Hetherington will act as secretary of the Committee, and all communications on the subject should be addressed to him at the Ministry of Health, Whitehall. London, S.W.

PULMONARY AND INTESTINAL EMBOLISM SECONDARY TO PHLEBITIS OF THE LEG.

AT a meeting of the Société Médicale des Hôpitaux of Paris on Nov. 12th, 1920, M. Jules Amaudrut reported the following case, which is of interest from the standpoints of both pathology and therapeutics. A woman, aged 36 years, was admitted into hospital on July 26th, 1920, for phlebitis of one of the branches of the right external saphenous vein. On the postero-external surface of the calf was a little indurated sinuous cord, tender on pressure, with slight swelling of the surrounding tissues. The temperature ranged from 100·4° to 102·2° F. The limb was immobilised on a splint. The patient's condition remained stationary for a week. Then suddenly, on August 1st, an abundant bloody stool was passed. It consisted of red and blackish blood and black clots. There was no abdominal pain or tenderness. The general condition became worse, the face was slightly drawn, the pulse 130 and small, the respiration rapid. Ice was applied to the abdomen. During the day two other stools, less abundant but blackish, were passed. In the evening the patient's condition was better, the abdomen was slightly distended, but only slightly painful. On August 2nd there was another abundant hæmorrhagic stool followed by the same general symptoms. This general condition improved, but on the afternoon of August 4th the patient was seized with violent pain at the base of the chest on the right side, accompanied by intense dyspnœa, incessant fits of coughing, and expectoration of red and blackish blood. Examination of the right base showed slight dullness and crepitant râles of different sizes. The general symptoms were grave; the face was drawn, the pulse small and almost uncountable, and there were cold sweats. Morphine was injected at the site of pain and stimulants were given. In the evening the temperature was 103°. On the 5th the general condition was better, the pulse was 140, and the dyspnœa less. The pain in the side was still violent and the expectoration continued. On the 6th the symptoms of the 4th were repeated, but the pain was localised at the right shoulder, and the hæmoptysis was increased. Crepitant râles were heard all over the summit of the lung. This fresh embolism much aggravated the condition of the patient. On the following days improvement took place and the temperature fell to 100·4°. The expectoration gradually changed until it became like liquorice-juice, and then it became purulent. Auscultation always showed two foci of râles—at the base and apex—where there was also dullness with increased vocal fremitus. From the 10th signs of a cavity in each of these situations, but especially at the apex, developed. The expectoration became abundant and fœtid and the temperature hectic. A bedsore formed over the sacrum. On the 16th artificial pneumothorax was induced by injecting first 200 c.cm. of oxygen and then 800 c.cm. of nitrogen. On the following day the purulent expectoration was a little less abundant. On the 17th 1000 c.cm. of nitrogen were injected. On the 18th the expectoration had considerably diminished and 1500 c.cm. of nitrogen were injected. After this improvement was rapid; the temperature became normal in 24 hours and the expectoration was reduced to a few muco-purulent *crachats*.

PLAGUE IN PARIS.

IT has been known for some time that sporadic cases of plague have been occurring in Paris, and the fact that the diagnosis and treatment of plague formed the subjects of articles in the lay as well as the medical press made a question in the French Chamber pertinent. No figures of plague mortality have appeared in the official reports, but the censorship seems to be relaxing somewhat if we may judge from a series of six articles which appeared recently in *Bulletins et Mémoires de la Société Médicale des Hôpitaux de Paris* for Jan. 6th, 1921. The existence of an epidemic lasting from May to October is frankly admitted in a paper by Dr. E. Dujardin-Beaumetz and Dr. Edouard Joltrain, though they add that it is now nearly ended. The Paris authorities would be well-advised to take the public more fully into their confidence, for plague has to be fought with public coöperation.

THE Anniversary Dinner of the Medical Society of London takes place at the Wharncliffe Rooms, Hotel Great Central, on Tuesday, March 8th, at 7.30 P.M.

THE Hunterian Oration will be delivered at the Royal College of Surgeons of England, by Sir Charters Symonds, at 4 P.M., on Monday, Feb. 14th. On that evening H.R.H. the Prince of Wales will dine at the College with the President and Council. During the dinner the Prince will be admitted to the Fellowship; his diploma will be handed to him after his health has been proposed, and he will sign the roll.

AT a special meeting of King Edward's Hospital Fund for London, held at St. James's Palace on Jan. 26th, a report was presented containing specific resolutions for the preservation of hospital management and control. These were adopted and ordered to be forwarded to the Prime Minister, the Minister of Health, and the members of the Government Committee of Inquiry.

THE Milroy lectures of the Royal College of Physicians of London will be delivered by Dr. Martin Flack on Feb. 17th, 22nd, and 24th, his subject being Respiratory Efficiency in Relation to Health and Disease. For his Goulstonian lectures on March 1st, 3rd, and 8th Dr. George Graham has chosen Glycæmia and Glycosuria. The Lumleian lectures by Dr. A. Whitfield on March 10th, 15th, and 17th will deal with Some Points in the Ætiology of Skin Diseases.

THE Marquess of Linlithgow, on the nomination of the Secretary for Scotland, and Sir W. B. Peat, of the firm of W. B. Peat and Co., chartered accountants, have been appointed to the Committee which is inquiring into the financial position of the voluntary hospitals. The first full meeting of the Committee took place at the Ministry of Health on Wednesday, when evidence was given by Sir Arthur Stanley, Sir Napier Burnett, Lord Knutsford, and Mr. E. W. Morris.

DONATIONS AND BEQUESTS.—Miss Christina Christie, Rose Cottage, Oyne, now residing at Colorado, U.S.A., has sent a donation of £600 for the purpose of endowing a bed for the parish of Oyne in the War Memorial Cottage Hospital for Insch and district, and also £50 for the Oyne parish bed.—The proceeds, amounting to £146, from two successful fancy-dress balls recently held in the town hall, Banchory, were handed to Sir James Taggart's Fund for the Aberdeen Sick Children's Hospital.—The Great Northern Central Hospital, London, has recently received £22 from Miss L. McDonald (proceeds of entertainment at Camden House School) and £10 10s. from National Union of Teachers.

A COMPARISON OF THE USE OF BROWN AND WHITE SUGARS FOR PLAIN COOKING.

BY MARION C. SOAR, B.SC., F.C.S.,
HOUSEHOLD AND SOCIAL SCIENCE DEPARTMENT, KING'S COLLEGE FOR WOMEN, CAMPDEN HILL-ROAD, W.

DURING the rationing and shortage of white sugar, and when brown sugars were relatively easy and less expensive to obtain, many institutions, such as schools and hostels of various kinds, used brown sugars in cooking to a large extent, and discussions subsequently arose comparing brown and white sugars for plain cooking. Of course, where the colour of the cooked food is a matter of importance it is impossible to obtain good results with a coloured sugar, but experience of brown sugars in cooking seems to prove that the colour is the only serious disadvantage apparent in their use for ordinary cooking purposes.

Results of Analyses.

In order further to compare brown sugars with white an examination was carried out of some brown sugars collected from various sources. Each sample was obtained from a different shop and a different locality.

The determinations made were as follows:—

Percentage of (*a*) water; (*b*) ash; (*c*) cane sugar; (*d*) reducing sugars calculated as invert sugar. White granulated rationed sugar was used for comparison.

Sugar content.—The rationed sugar contained over 99 per cent. of cane sugar, only 0·5 per cent. of invert sugar, and a negligible quantity of water and ash. Of six samples of brown sugar examined—varying in colour from yellow to a dark brown—only two contained less than 90 per cent. of cane sugar, and in these two cases the deficiency of cane sugar was made up by a higher percentage of invert sugar. Two others contained approximately 92 per cent. of cane sugar, and the remaining two examined 95 per cent. The percentage of invert sugar ranged between 1 and 5, so that the percentage of total sugar (cane and invert) varied between 90 and 98, the average content being approximately 93 per cent.

Sweetening power.—The results of the total sugar content of the samples show that in sweetening power the average brown sugar compares unfavourably with a white sugar because it contains less sugar. The fact that part of its sugar is invert sugar is immaterial, as it is generally recognised that, though cane sugar has a greater initial sweetening effect upon the palate, the effect of invert sugar is more lasting, and in its total effect seems to be the sweeter of the two. In sweetening acid-containing substances the quicker sweetening effect of cane sugar is an advantage, as the acid effect upon the palate is immediate; but for most purposes the presence of a small percentage of invert sugar with the cane sugar is not a disadvantage.

Contents not sugar.—None of the sugars contained any albuminoid matter, and the ash content in every case was below 1 per cent., so that the sugars could not have been adulterated by any coarse adulteration, such as a fine sand. Though this kind of adulteration is not often met with nowadays, the difficulty of obtaining white sugar and the consequent increase in the sale of the brown might have been an incentive to the use of adulterants.

Two yellow sugars were examined for the presence of aniline dyes, but, as expected, none was found.

The water content of the sugars was also not high enough to indicate adulteration, the highest content of water being 4 per cent. and the average 2 per cent.

The impurities met with in the sugars were therefore evidently only those usual to raw sugars and due to incomplete refinement. In all cases the sugars dissolved readily to give a fairly clear solution, though, of course, coloured. There was only one sample which showed insoluble matter, which consisted of small wood shavings, which certainly would be objectionable in cooking, but were probably due to either lack of refinement or imperfect packing and storage.

Conclusions.

It is of very little value just now with fluctuating prices to make a comparison of the relative cost of brown and white sugars, but in buying brown sugar merely because of the lower cost the probable lower sugar content should be taken into consideration. From the analyses made there seems to be no objection to substituting brown for white sugar in plain cooking, except in the result upon the colour of the food when cooked. The colour of a brown sugar can be readily and simply removed by filtering a solution of the sugar through animal charcoal, but this would be impracticable for most households.

The adulterations found were merely such accidental impurities as would be removed upon further refinement of the sugar.

TUBERCULOSIS.

Sanatorium Mismanagement.

"You will not get results, gentlemen, until you reform the management of your public sanatoria for your poorer classes."

IN the bulky volume[1] in which the *Transactions of the National Association for the Prevention of Tuberculosis* (Eighth Annual Conference) have just been published there is the inevitable mixture of platitudinous and inspiring papers. Two of the latter type deserve special prominence, as their authors show that candour which is seldom aired at congresses except when only two or three are gathered together in the intervals between the official speeches. Speaking about sanatorium treatment, Dr. Charles L. Minor, of North Carolina, contrasted the achievements of private and public sanatoriums, pointing out that the successes of the former are traceable to that skilled, individualising, and interested treatment which is seldom obtainable in public institutions. These, he thinks, are apt to be exploited by medical officers of the come-and-go stamp as a stepping-stone to something better.

"The close personal relation of patient and doctor is usually lacking, yet in this disease such a relation is essential, and then you expect to get results. You will not get results, gentlemen, until you reform the management of your public sanatoria for your poorer classes."

Another point on which Dr. Minor was emphatic was the necessity for keeping early and late cases apart.

"...... if you expect to mix together your advanced hopeless cases and your incipient cases you will get few good results."

Speaking as the superintendent of a private sanatorium, he argued that the best arrangement provided separate quarters for advanced, moderately advanced, and incipient cases, so that patients in the last class should not hear the coughs nor see the coffins of patients in the first class.

"I get excellent results in people of modest means, and when you get proper conditions for those poor people, men put over them who will put their whole heart and soul and mind into their work and into each individual patient, you will see a wonderful change."

In short, according to this critic, sanatorium treatment for the working classes has failed because it is not sanatorium treatment, but a dismal parody; and medical officers who have worked in both private and public sanatoriums in this country will surely admit there is some truth in this unpalatable diagnosis. More cautious in his wording, but equally conscious of the need for reforms, Sir Henry Gauvain deplored the medical education that taught the student more about the internal economy of the frog than about tuberculosis. Both from what he said and what he implied it was evident that his criticism was directed rather against the educational system than the medical officer it evolved, but he also made the valuable suggestion that, as a check on the individual, candidates for the tuberculosis service might be first appointed, with adequate remuneration, as probationary tuberculosis officers, and that only after they have shown complete evidence of their fitness for their duties should they be transferred to the permanent staff.

The Ætiology of Post-influenzal Pulmonary Tuberculosis.

Among the many recent papers on the relation of influenza to pulmonary tuberculosis two are of special interest because they throw light on the origin of post-influenzal pulmonary tuberculosis and show clearly the salient differences between this condition and non-influenzal tuberculosis. Dr. O. Kieffer,[2] of the Municipal Chest Hospital in Mannheim, has found that 55 of his patients, or 20 per cent. of all the admissions to his hospital between Dec. 1st, 1918, and June 1st, 1919, had developed the first signs of pulmonary tuberculosis in connexion with an attack of influenza. As a class, these patients were characterised by comparatively good physique, absence of a personal or family history of tuberculosis, and by the rapidly progressive nature of the tuberculosis, which often proved fatal in a few months. These patients, mostly young adults, failed to react to v. Pirquet's test, betraying in this respect a sinister resemblance to patients with measles. But the most instructive and distinctive feature of these cases was the X ray evidence. Skiagrams taken sufficiently early in the disease were curiously uniform, showing massive tumour-like shadows in the hilus region, on one or both sides. In early cases the lungs themselves threw no abnormal shadows, and the X ray picture was exactly identical with that of hilus tuberculosis in childhood. Between this early stage and the advanced stage, with only the apices of the lungs intact, there were intermediate stages, showing the radiating spread of the disease from the hilus. In a study of post-influenzal tuberculosis, as observed at Nakkebölleſjord Sanatorium in Denmark, Dr. S. M. Saxtorph[3] confirms Dr. Kieffer's findings in almost every respect. He notes that there seemed to be little or no connexion between the severity of the influenza and that of the subsequent tuberculosis. As illustrating the origin of the pulmonary disease in the hilus he records the case of a woman, aged 33, with no family or personal history of tuberculosis. In November, 1918, she contracted influenza, and was confined to bed almost for a month. No tubercle bacilli could be found in her scanty sputum, but she continued to cough and lose weight and to complain of lassitude, anorexia, and night sweats. There were doubtful signs over the front of the right lung, and the evidence of the fluorescent screen was indefinite, but a skiagram clearly showed abnormal hilus shadows on both sides, and beaded, radiating shadows, passing from the hilus to both the lungs, the apices of which were perfectly clear. Dr. Saxtorph suggests that in the many cases of post-influenzal lassitude and debility, with cough, night sweats, and subfebrile temperatures, reactivation of an old hilus tuberculosis is to blame. Truly, as Dr. A. K. Krause has said, "the patient is as resistant as the shell of his tubercle"; and when influenza is prevalent the resistance of this shell, as evolved by a dense, fibrotic reaction to repeated stimuli, often determines the patient's fate.

The International Artificial Pneumothorax Society.

This society was originally established as a bond of union between medical men interested in artificial pneumothorax all over the world. Now that this treatment has received general recognition the society has modified its programme, limiting its functions to that of a central exchange, so as to enable its members to direct their patients, when travelling abroad, to fellow members and experts in this highly technical treatment. In the past patients, who travelled afar and who required refills without the inconveniences of returning home for this purpose, have often experienced difficulties in finding practitioners expert in this treatment. The cost of membership is Fr.5, which should be sent to Professor Carpi, Lugano, Switzerland.

SELBORNE SOCIETY.—The Ramble Section of this society is paying a visit to Middlesex Hospital and Medical School on Saturday, Feb. 5th, meeting outside the hospital at 2.30 P.M.

CANADA.

(FROM OUR OWN CORRESPONDENT.)

Ten Years of Public Health in Ontario.

ACCORDING to Dr. J. W. S. McCullough, chief officer of health for the province of Ontario, considerable advance has been made in public health matters in spite of the fact that during half of the decade the war was in progress. At the beginning of the period the Board of Health had undertaken to consolidate the Public Health Laws, to assist the antituberculosis campaign, to further education concerning prevention of disease, and to improve the methods of administration. The Ontario Health Act was consolidated in 1912, with a view to assisting local authorities and medical officers of health. A number of district medical officers were appointed, but county officers under the Provincial Board of Health have not yet been installed. Local appointments of medical officers of health now imply some degree of permanency; previously the office changed hands every year. Moreover, the medical officer, who was formerly grossly underpaid, can now secure a proper adjustment of his salary on application to the county judge. Many full-time men in the larger cities are receiving a fair remuneration, and each year sees fewer salary disputes and fewer efforts to secure the dismissal of medical officers of health.

The number of sanatoriums in Ontario has grown from 10 in 1910 to 25 in 1920. The provincial Government now provides an amount up to $4000 towards the cost of building a sanatorium, and grants the sum of $3.50 weekly towards the cost of maintenance of each patient. As the results of this policy the annual grants for maintenance have increased year by year from $26,000 in 1910 to $279,000 in 1919. The accommodation for patients in sanatoriums, amongst which are included several preventoriums, is about 2000, as compared with 615 ten years ago. Practically the whole cost of the antituberculosis work in Canada, with the exception of the Federal Government's annual grant of $10,000 to the Canadian Association for the Prevention of Tuberculosis, has been borne by the provinces. During the present year, for exhibition purposes and educational campaigns, the Ontario Board of Health has at its disposal $9000. In 1914 the Provincial Board began to supply county boards with antitoxin at about one-third its commercial price. Two years ago tetanus antitoxin, typhoid, pertussis and small-pox vaccines, anti-meningitis serum, preventive treatment of rabies, and gonorrhœal ophthalmia were first supplied entirely free to physicians, boards of health, and the public generally. During the war the Board's laboratory in Toronto supplied almost all the typhoid and paratyphoid vaccine used by the Canadian Army; these were furnished free of cost—which would have been approximately a quarter of a million dollars—to the Department of the Canadian Militia.

Some years ago the Board began to establish laboratories. There were two of these in 1910, and their number will shortly be increased to seven. The Toronto laboratory, whose main work is the manufacture of pertussis, typhoid, and paratyphoid vaccines, has recently added that of phenarsenamine, which will be supplied free to clinics, to hospitals, and to boards of health.

The Canadian Medical Association Journal.

This journal is shortly to be enlarged; in a year or two a change from monthly to semi-monthly publication is contemplated, and later a weekly issue will be attempted. The Ontario Medical Association, which recently negotiated for an official journal of its own, has thrown in its lot with the national medical journal; the latter will contain news and editorial matter which will be of interest to the medical profession throughout Canada.

Medical Students at the University of Toronto.

The official figures given by the registrar of the University of Toronto show an attendance of 4566 students in all branches. In the Department of Medicine in 1914-15 there were 660 medical students: in

1919-20 there were 1284 registered; in 1920-21, 1009. The medical staff was increased from 145 in 1914-15 to 189 in 1920-21. The proposal has recently been made to limit to 90 the number of students admitted to the faculty of medicine each year. Some objection has been raised to this; the University of Toronto is a State-aided institution largely financed by the Ontario Government, and it is felt to be unfair to exclude anyone desirous of pursuing medical studies in the provincial university. It is doubtful if the Ontario Legislature—now composed largely of farmers and labour members—would support any limitation of the number of medical students in that province.

Deaths from Diphtheria in Ontario.

Dr. J. G. Fitzgerald, professor of hygiene in the University of Toronto, and director of the Connaught Laboratories of the Ontario Board of Health, has recently made an analysis of the deaths from diphtheria in Ontario for the years 1880 to 1918 inclusive. The fall in the death-rate is particularly noticeable from 1906 to 1918. Despite a steady increase of population from 1,884,000 in 1880 to 2,800,000 in 1918, the total number of diphtheria deaths fell from 1251 to 335 in the years named. An interesting comparison is made of deaths from diphtheria in and out of hospital. In seven consecutive years the percentages are as follows:—

	1912.	*1913.*	*1914.*	*1915.*	*1916.*	*1917.*	*1918.*
In hospital	8·0	6·15	7·82	6·51	7·00	4·18	6·40
Out of hospital ...	12·63	10·10	10·29	12·91	13·14	10·90	19·62

A considerable number of patients were admitted to hospital in a moribund condition, dying within 24 hours of admission.

AUSTRALIA.

(FROM OUR OWN CORRESPONDENT.)

Illness of the Governor-General.

SHORTLY after fulfilling social engagements during "Race Week" (first week in November) in Melbourne it was announced that Lord Forster was suffering from a severe attack of tonsillitis. A day or two later a further announcement was made that the illness was diphtheria. The disease ran a favourable course, and His Excellency was able to leave for Sydney on Dec. 1st, where he will continue in residence for some weeks. No other cases were reported among the staff at Federal Government House. Diphtheria has continued to prevail almost in epidemic form in Victoria for the past seven or eight years, and although the death-rate has been comparatively low, upwards of 2000 deaths have occurred during the period.

University Finances.

The special appeal to the public for a sum of £100,000 by the Melbourne University has not so far resulted in any notable response. Upwards of £30,000 has been subscribed in small sums, and it is possible another £20,000 will be reached apart from any large gift. The Sydney University has decided to raise the fees in all schools next year, in some instances as much as 50 per cent. The high cost of materials is given as a reason for the step.

Lumbar Puncture and Meningitis.

At the October meeting of the Victorian branch of the British Medical Association Dr. R. Webster, pathologist to the Children's Hospital, Melbourne, read the results of experimental work undertaken to test the possibility of setting up a meningitis by lumbar puncture. Dr. Webster stated that when he undertook the investigation he was unaware that some American observers had published conclusions based on similar work, and he purposely avoided consulting their paper until his own results were complete. Dr. Webster said: "I feel warranted in urging that the lumbar puncture needle should not be employed except in the presence of definite clinical signs of meningitis, and in deprecating its use as a possible royal road to the diagnosis of an obscure condition." Dr. Webster concluded there was definite risk of infecting the spinal meninges by lumbar puncture in the presence of a severe septicæmia. Once decided upon, as small an amount of fluid should be removed as is consistent with diagnostic requirement. His experiments were performed upon monkeys and employing the pneumococcus as the infecting organism.

Prohibition.

The polls on the liquor question recently taken in Victoria and Queensland have resulted in a general defeat of the prohibitionists. In Victoria only two small licensing districts voted "No licence." The figures generally disclose the fact that public opinion is somewhat evenly divided, and that results might swing either way if a simple majority of votes determined the result. It is possible that in Victoria local option polls will be abolished in favour of the Licence Reduction Board, a semi-judicial body which has been in successful operation for over 12 years and has closed more than 1300 hotels in that time. In New South Wales this legislation has been copied owing to the failure of local option polls in that State. In Queensland the local branch of the B.M.A. carried a motion favouring prohibition.

Dec. 8th, 1920.

Public Health.

ANNUAL REPORTS OF MEDICAL OFFICERS OF HEALTH.

CITY OF EDINBURGH.

IN his annual report for the year 1919 Dr. A. Maxwell Williamson points out that there are certain wards within the city which, with unvarying regularity, occupy the unenviable position of having excessive mortality from nearly all causes. In Edinburgh, as in nearly all large centres of population, there are wards where death-rates are so much in excess of the average as to render the conditions prevalent in them subject-matter for serious consideration. These conditions are, of course, intimately associated with defective housing. In insanitary overcrowded districts the sickness and death-rates are generally in excess of the mean average. During the year there were 5583 deaths within the city boundaries, giving a death-rate of 16·5 per 1000. This relatively high rate is, in part at least, attributable to the outbreak of influenza which visited the city in the early part of 1919 and increased the rate in round figures by 2 per 1000.

Treatment of tuberculosis.—Tuberculous disease yields slowly to the efforts which are being made in Edinburgh towards effectively dealing with it. The number of cases notified was slightly below that for the previous year and constitutes the lowest figure yet attained. There were, however, 602 cases of pulmonary tuberculosis notified in addition to a considerable number of notifications of tuberculous disease affecting organs other than the lungs. Of the 602 notified cases, 359 received institutional treatment. Many of the patients in the early stage of the disease improved markedly in health or were cured, while the advanced cases, which eventually proved fatal while under treatment in hospital, experienced the advantages of a well-appointed sanatorium, and their friends were relieved of the anxieties and risks inseparable from attendance on a sufferer in an advanced state of the disease. At the Royal Victoria Dispensary every effort was made to detect cases of phthisis in the early stages of the disease with a view to immediate treatment, and, in Dr. Williamson's opinion, the tuberculosis dispensary may possibly hold out more hope in connexion with the general crusade against tuberculosis than is contributed by other branches of the work. In this connexion, however, he repeats what he has often said before—namely, that the real hope of ultimate success in overcoming the disease rests not in the multiplying of sanatoriums, or even tuberculosis dispensaries, but is centred in the accession of a supply of suitable and sanitary housing accommodation. Much of the expense at present incurred on the provision of institutions for the cure of phthisis might well be diverted toward the object of prevention rather than by lavishing expenditure on efforts to cure, which, it is submitted, yield returns not commensurate with the financial outlay involved.

Isolation of measles.—For many years Dr. Williamson has wished to have more beds available for the isolation and treatment of measles. The Scottish Board of Health are now directing attention to its importance, and it is hoped that amalgamation and reorganisation may set free beds for the treatment of this disease. The existing somewhat restricted accommodation in Edinburgh has, however, been utilised to the fullest extent. The most serious cases and those most urgently requiring removal on account of their surroundings were regarded as having the first claim upon the available accommodation. It was found possible during the year to remove 500 cases of the malady to hospital. The total mortality-rate of this disease amongst those treated in hospital amounted to 10·1 per cent., as contrasted with a similar rate of 2·4 per cent. in the case of scarlet fever. This serves to emphasise the fact that measles, more particularly in young children, is more to be feared than many other forms of infectious disease, though it is popularly regarded as of relatively small importance.

METROPOLITAN BOROUGH OF ST. PANCRAS.

Dr. T. Shadick Higgins, in his annual report for 1919, has the satisfaction of recording the fact that the mortality in the borough during the year under report was the lowest on record, in spite of the fact that the ravages of the influenza epidemic continued during the earlier months. For the first time the net St. Pancras deaths for the year were less than 3000, and the annual death-rate was down to 13·4 per 1000 civil population. The deaths of infants under one year of age also were less in number than in any previous year, the rate being 88 per 1000 births. In Dr. Higgins's opinion, however, the deaths of infants remain more numerous than they need be, and much patient effort to reduce their number is still required. In regard to births, the continuous decline which had been observed during the war reached its greatest depth in the middle of 1919, but during the last two quarters there was a marked increase and the birth-rate for the year as a whole amounted to 16·7 per 1000 of the total population. As a result of the favourable variation in the births and deaths there was an excess of births over deaths of 891 for the year, as compared with an excess of deaths over births of 596 which was recorded in 1918. In reference to infectious diseases, the outstanding feature of the year was the cessation of the outbreak of influenza. This raged during part of the summer and autumn of 1918, and was still grave in the spring of 1919, but had almost spent itself by the end of the first quarter, since which time there has been no serious recrudescence. The total St. Pancras deaths certified during 1919 as being caused by this disease numbered 260, as compared with 700 in the previous year, but the number of deaths actually due to the epidemic was no doubt even greater than these figures indicate. The mortality from tuberculosis, amounting to 341 deaths, was lower than usual, and from both measles and whooping-cough much lower than for many years. Scarlet fever was more prevalent than in the previous three years, though the deaths were few, the cases being of a mild character. There was no increase in the prevalence of diphtheria. Typhoid fever reached a lower point than ever before, only seven cases being notified, and it is satisfactory to note that the decline in cerebro-spinal fever, which has taken place since the outbreak of 1915, was continued. A considerable number of men suffering from malaria and dysentery acquired abroad on active service have returned to civil life, but there appears to be no tendency for the disease to spread, not one case acquired in England having been reported in St. Pancras.

SCHOOL MEDICAL SERVICE.

HEALTH OF SCHOOL CHILDREN IN BELFAST.

A discussion has been going on in the Belfast press upon the condition of the primary schools of the city and its relation to the health of the children in attendance upon them. There are over 300 primary schools in Belfast under the direction of the Board of National Education. In a certain proportion of cases two schools are lodged in the same building. Most of the newer schools are good and many of them are excellent. But there are about 80 old schools whose condition has long been recognised as a source of danger to the children, and a serious reproach to a wealthy and progressive community. Many of these schools were constructed as appanages to various churches and are totally unsuitable for educational purposes. Some of them consist of a single large apartment, with, perhaps, one small adjoining class-room. As a result several classes are conducted in the same room, involving noise, slackness of discipline, and a heavy tax upon the nerves of both teachers and scholars. Many of them abut upon noisy and crowded thoroughfares, and ventilation is sacrificed to the necessity of comparative quiet. The sanitary arrangements are in many cases deplorably defective, and cleanliness leaves much to be desired. A large percentage of the older schools are destitute of playgrounds, and at the interval the children have the alternative of either turning out into the streets or taking their relaxation and their lunch in a stuffy apartment of which the air has been fouled by several hours of continual school. There is no medical inspection, and the way to the dissemination of infectious disease is left open. Further, the increase of school accommodation has not kept pace with the increase of population of the city. There are in round numbers 70,000 children of school age in Belfast. If overcrowding were strictly prohibited and the necessary amount of air- and floor-space secured for each scholar the present accommodation would suffice for only some 55,000 scholars. It is impossible to say precisely how many children are deprived of all education, but it is clear that in the present deficiency of accommodation it is not easy to enforce the law of compulsory attendance.

It cannot be said that the city has been indifferent to the above deplorable state of affairs. It is more than a generation ago since the late Dr. W. A. MacKeown pointed out the defects which existed at that period and the resulting dangers to the health of the children. These matters have been repeatedly ventilated in the press and at public meetings. Several occupants of the Lord Mayoral chair, notably Lord Shaftesbury and the late Alderman R. J. McMordie, interested themselves in this question, but found their efforts frustrated by legal difficulties. Under the National Board system there is no power on the part of local authorities to provide schools adequate to the needs of the population. There is no local education rate. When a new school is needed some individual, often a clergyman, has to raise one-third of the prospective outlay upon buildings before any help is available from the National Board. That such a system should have lasted for nearly a century shows with how little wisdom the world is governed. When Mr. Long was Chief Secretary for Ireland a deputation waited upon him in Belfast and pressed these matters upon his attention. He heard the deputation courteously and did not dispute their facts, but his reply amounted to this: "Help yourselves; *provide the requisite funds* for the proposed reforms." Unhappily, it required legislation to carry out this admirable advice, and politicians were shy of the difficulties surrounding Irish primary education. There was a deadlock, and that deadlock still continues. Mr. MacPherson tried his hand at the question, with what success all the world knows. The religious difficulty is, unhappily, acute in Ireland, and tends to stop the wheels of educational progress.

The new political regime in Ireland may open a new era in education. There can be little doubt that one of the first tasks of the Ulster Parliament will be to deal with the question of primary education. Many of the old schools must be swept away. New schools must be constructed to meet the present clamant needs, and they must be up to the full modern standard, both from the point of view of education and of health. Medical inspection must be enforced and treatment centres for children instituted. The cost need not be large. Experience in England and Wales shows that it averages about 2*d.* per child. A proper standard for teachers must be set up and remuneration must be adequate. To what extent tuberculous infection occurs in childhood and remains latent until adolescence or early adult life is a question to which no final answer can yet be given, but the possibility cannot be denied, and many would probably go further and affirm that this mode of infection is common. If this view is sound, the hygiene of schools becomes a matter of urgent importance, apart from its importance from other points of view. That infectious disease—measles, scarlet fever, diphtheria, &c.—is often contracted at school admits of no doubt. England was late in adopting the principle of the medical inspection of schools and school children, and the Act applying to Ireland is so hedged in by restrictions as to be practically inoperative. It is a matter urgently calling for attention.

REPORT OF SCHOOL MEDICAL OFFICER FOR SHEFFIELD.

IT was not found possible to resume the routine inspection of school children at Sheffield until April, 1919, when a commencement was made with the group of leavers, followed in October by that of entrants. The total number so examined was 12,931, but, in addition to these, 23,379 special cases were seen at the schools. The defects requiring treatment most frequently found in the routine inspections were those of vision (1443) and of the nose and throat (1112); and, in addition to these numbers, amongst the children specially examined there were found to be 2215 and 1545 respectively needing treatment for these two conditions. Organic heart disease was diagnosed in 103 cases in the code groups (0·8 per cent.), 73 being recommended for treatment and 30 being kept under observation. There was no defective nutrition of any importance among the Sheffield children, only 8 being found to need treatment in the code groups and 27 among those specially brought forward. Not a single case of definite pulmonary tuberculosis from among the 13,000 children examined in the code groups was referred for treatment, and only 3 children were recommended to be kept under observation for this disease. This is a noteworthy fact in a large industrial city such as Sheffield. The existence of the disease was suspected in 35 children (in the code groups), and in 39 others specially examined (of whom 24 and 37 were respectively recommended for treatment). In the section of the report dealing with physically defective children, it is stated (p. 43) that 312 children "liable to school attendance" are suffering from "crippling due to tuberculosis," of whom 44 are attending public elementary schools. Out of the 12,931 children systematically examined only 8, and among the 23,379 special cases only 27, were found to be suffering from malnutrition. Infectious skin diseases (ringworm, scabies, impetigo, &c.) were not especially prevalent in the code group children (257 cases in all); but, in his report on the work of the X Ray and Skin Department, Dr. E. F. Skinner tabulates 8745 cases including 1158 ringworm, 4159 impetigo and sore head, and 1634 scabies. The increase in scabies, due to infection from "the front," is shown by comparison of the average weekly number admitted to the school clinic (3.45) in 1912 with that in 1918, which was 54·63. Under the treatment formerly used there had been an average of 56 days exclusion from school; by the adoption of bath treatment the exclusion was reduced to an average of 12 days. The cost was practically the same, and whereas under the old system of home treatment 5·46 per cent. became re-infected, with the bathed cases the percentage was only 1·03. The efficiency is entirely due to adequate supervision by the nurses in charge. With regard to defective vision, 1443 children were referred for treatment out of the total 11,917 examined, or 12·11 per cent. Details are furnished as to the cases treated, numbering 3473 in all, of whom 1755 were boys and 1718 girls. Among boys there were 648 cases of hypermetropia and hypermetropic astigmatism, and 106 of myopia and myopic astigmatism; also 63 cases of mixed astigmatism. Among girls the respective numbers were 674, 125, and 118; 576 boys and 458 girls were treated for squint. One of the most difficult conditions to treat satisfactorily in school children is that of chronic ear discharge; of 450 such cases, 96 only were returned as cured or improved. Of 377 cases of deafness without discharge, 166 were cured or improved. It is noted, however, that attendance is becoming more regular now that the war is over. Dr. Thomas Chetwood, who presents this report as school medical officer, regrets the recent decision of the School Management Sub-committee that playgrounds and public parks cannot usually be regarded as satisfactory class-rooms. At Whiteley Wood Open-air School, which was open from March to December, there were 119 children in average attendance; 93 were found fit to return to ordinary school attendance at the end of the year. Physical training and organised games are carried out with excellent results on the health of the children, accompanied by "a marked increase in alertness." Mr. Henry Cole, however, the training superintendent, points out that a cinder surface for the recreation ground is unsuitable.

URBAN VITAL STATISTICS.

(Week ended Jan. 22nd, 1921.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate population estimated at 18½ million persons, the annual rate of mortality, which had been 16·6, 14·0, and 12·8 in the three preceding weeks, rose to 13·3 per 1000. In London, with a population of 4½ million persons, the death-rate was 12·9, or 0·3 per 1000 above that recorded in the previous week, while among the remaining towns the ratio ranged from 4·5 in Ipswich, 6·2 in Ealing, and 6·4 in Edmonton to 20·7 in Tynemouth, 21·8 in Preston, and 22·5 in Middlesbrough. The principal epidemic diseases caused 223 deaths, which corresponded to an annual rate of 0·6 per 1000, and comprised 72 from diphtheria, 71 from infantile diarrhœa, 35 from whooping-cough, 29 from measles, 12 from scarlet fever, and 4 from enteric fever. Measles caused a death-rate of 3·2 in Middlesbrough, whooping-cough of 1·7 in Newport (Mon.), and diphtheria of 1·0 in East Ham. There were 4350 cases of scarlet fever, 2618 of diphtheria, and 1 of small-pox under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 4413, 2597, and 1 respectively at the end of the previous week. The causes of 40 of the 4746 deaths in the 96 towns were uncertified, of which 9 were registered in Birmingham, 5 in Gateshead, 4 in Hull, and 3 in Liverpool.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 18·4, 18·4, and 15·9 in the three preceding weeks, was 15·8 per 1000. The 329 deaths in Glasgow corresponded to an annual rate of 15·6 per 1000, and included 8 from whooping-cough, 4 from diphtheria, 3 from infantile diarrhœa, 2 each from small-pox and measles, and 1 each from enteric fever and scarlet fever. The 150 deaths in Edinburgh were equal to a rate of 17·5 per 1000, and included 4 from influenza, 3 from measles, and 2 each from diphtheria and infantile diarrhœa.

Irish Towns.—The 135 deaths in Dublin corresponded to an annual rate of 16·6, or 1·3 per 1000 below that recorded in the previous week, and included 2 each from whooping-cough, diphtheria, and infantile diarrhœa. The 148 deaths in Belfast were equal to a rate of 18·5 per 1000, and included 6 from whooping-cough, 3 from infantile diarrhœa, and 2 from measles.

LITERARY INTELLIGENCE.—Mr. Henry Kimpton will publish shortly the following new books and new editions:—"Psychopathology," by Edward J. Kempf, M.D.; "Block Anæsthesia and Allied Subjects, with Special Chapters on the Maxillary Sinus, the Tonsils, and Neuralgias of the Nervus Trigeminus," by Arthur E. Smith, D.D.S., M.D.; "Hygiene, Dental and General, by Clair Elsmere Turner, with chapters on Dental Hygiene and Oral Prophylaxis by William Rice; "Dental Pathology and Therapeutics," by Henry H. Burchard, M.D., D.D.S., sixth edition. Rewritten by Otto E. Inglis, D.D.S.

Correspondence.

"Audi alteram partem."

PROGNOSIS IN ENCEPHALITIS LETHARGICA.

To the Editor of THE LANCET.

SIR,—In view of the notice which this disease is now receiving I am authorised by Sir George Newman to send a brief note on its prognosis so far as it appears from the collection of case reports made by me at the Ministry of Health.

A study of these reports, together with an examination of several old cases, shows that in many instances the later stages of the disease may be very prolonged and the source of much anxiety both to the patient and to his medical attendant. Facial and ocular palsies, marked paresis, and sometimes paralysis, of a limb or limbs, and tremors in the parts so affected are constantly mentioned as existing after the patient has resumed, or partially resumed, his normal occupation. In addition, the higher faculties are apt to remain for some time distinctly impaired, so that loss of memory, defects of speech, mental lethargy, and a general loss of intellectual tone result. The character, too, not uncommonly becomes changed, and often for the worse, especially in children. It may be noted in passing that MM. Harvier and Levaditi in a recent paper[1] support the conclusion reached by Marary—viz., that the sequelæ of epidemic encephalitis are often no more than the symptoms of a form of the disease with a prolonged evolution.

It will be recalled that soon after the disease appeared in this country and prior to Jan. 1st, 1919, when encephalitis lethargica became a notifiable disease under the Public Health (Acute Encephalitis Lethargica and Acute Polio-encephalitis) Regulations 1918, a special inquiry was initiated by the Ministry with the object of gaining information concerning the epidemiology and clinical characters of the disease. The material for investigation and the knowledge then available were both limited, but a full and carefully compiled report on the subject was issued by the Local Government Board in 1918.[2] At the time this report was issued the conclusions reached concerning the full course of the disease in individual cases and the ultimate fate of its victims were necessarily guarded and provisional in character. The mortality-rate, for instance, in Dr. MacNalty's series of 168 cases worked out at approximately 22 per cent. Of the 541 cases of encephalitis lethargica notified during 1919 from England and Wales, no less than 286 proved fatal—a mortality of 54·6 per cent. A later review of this series resulted in the elimination of a certain number of fatal cases by reason of mistaken diagnoses, but even so the death-rate figure remained at 50 per cent.—a mortality which is probably much higher than is generally supposed. The fatality is greatest in those over the age of 30.

I may add that the Ministry of Health, in conjunction with the Medical Research Council, are actively continuing the investigation of this disease in its epidemiological, clinical, and pathological aspects. This coördination has already resulted in the successful transmission of the virus of encephalitis lethargica to monkeys in the Derby case, which was reported in the annual report of the Chief Medical Officer of the Ministry for 1919-20. The detailed information regarding notified cases which we are receiving from the medical staffs of institutions, medical practitioners, and medical officers of health is proving of great value, not only as material for ultimate tabulation, but as a guide to the selection of cases for special investigation.

Possibly some of your readers can supply information on the after-history of cases notified during 1919, supplementary to that which they have already sent in reply to schedules of inquiry. Any such information would be specially welcome.—I am, Sir, yours faithfully,

ALLAN C. PARSONS,

Ministry of Health, Jan. 25th, 1921. Medical Officer.

MENTAL DEFECT AND CRIMINAL CONDUCT.

To the Editor of THE LANCET.

SIR,—In THE LANCET of Nov. 13th, 1920, there were published two interesting addresses by Sir Bryan Donkin on the mental condition of criminals and delinquents. I do not know whether he has heard of the advances in the treatment of delinquents which we have worked out in connexion with several of the criminal courts in various cities of the United States. I am myself at the head of the medical service attached to the Supreme Bench of Baltimore City, which was established by me, with the aid of the judges of the bench some five years ago. Every accused person who shows any signs of mental abnormality or who has a record as an habitual offender is examined mentally, and a report is made on his condition to the court before his trial.

Our medical service also deals with all questions of legal medicine that come up in connexion with our courts. In all cases of possible homicide the autopsy is either made by me or in my presence, and I report direct to the chief prosecuting officer. My office also takes care of other matters for the police, such as the investigation of blood stains, foot prints, and the like. I am also called into the Civil Courts as the court's expert on various questions, such as the credibility of a witness, the possible limits of pregnancy in bastardy cases, the wage-earning ability of men involved in non-support cases, &c. About half of my work is that of a psychiatrist; the other half includes all medico-legal questions. Our idea for our medical service is that it should be as it were the watcher at the gate of the Criminal Court, which examines all those who come to the gate, and turns aside into the proper institutions those cases that are mentally deficient or mentally diseased, or who show any symptoms that may make them unfit for confinement in a penal institution. In this way we attempt to keep out of our prisons the mentally deficient and the extreme physical cases, as well as those who are actively mentally disturbed. In short, we attempt to meet the very difficulty which was brought out in Sir Bryan Donkin's article, so that each case can be treated by the court, rather as an individual problem of badly adjusted personality than as a mere infraction of certain laws or regulations. In Chicago and in Boston there are these medical services attached to the courts, but they are more intimately connected with the purely mental side of the entire question.

I should be very glad to send you any further information about our medical service, if your readers are interested in the matter.

I am, Sir, yours faithfully,

JOHN R. OLIVER,

Medical Officer, Supreme Bench of Baltimore.

Baltimore, U.S.A., Jan. 12th, 1921.

THE DIET OF WELL-TO-DO CHILDREN.

To the Editor of THE LANCET.

Scene: O.P. Department of General Hospital, A.D. 1884.
Personæ: Mother with infant in arms (the latter crying and eating a piece of cake). Hospital House Physician.
H.P.: Well, what is the matter?
Mother: Baby has diarrhœa and vomiting.
H.P.: What do you feed your baby on?
Mother: A bit of what we have ourselves.
A severe lecture from H.P. to the mother on the iniquities of her treatment of a baby of 8 months old. Indignant mother leaves the hospital, saying that she, the mother of six healthy children, is not there to be lectured by a young boy!

SIR,—Was the mother right or was I right? The work of Sir Arbuthnot Lane during the last 20 years has brought forcibly before the profession a problem that it has to answer one way or the other. Is he right or not? If he is right then we have to accept that many chronic diseases, of the causes of which we have been in ignorance, are now proved by him to be in part, at least, if not entirely, due to intestinal stasis. There can be no doubt about the mechanical changes found in the bowel, for they can be seen frequently at operations by those who have eyes to see, and what is of almost equal importance, they have been shown to be present in cases, where no operation has been performed, in the truly wonderful X ray work of Dr. A. C. Jordan. As these changes are present there can be little doubt that some results must accrue from them, and those of us who are in general practice are quite familiar with the two types of cases described: the chronic invalid with general proptosis and continual abdominal discomfort, indigestion, and constipation; and the other type, who only suffers from a "difficulty with his bowels" or "his liver," as he prefers to call it, and who eventually develops cancer. These two types being familiar to us, are we to accept the conclusions which the author draws? That is to say, are we to prognose that the first type will develop cancer or rheumatoid arthritis in some distant organ or joint, and that the second type will get cancer locally? Or, in other words, that the person who has these changes well marked is doomed to disease sooner or later. It seems to me that this is very nearly a proved case, and that we are bound to accept the theory as a basis (for our conception) at any rate for the present, or until it can be proved by further research to be untrue. This, then, is a very serious position; certain well-known diseases of mortal importance to the sufferers, a definite anatomical cause accepted for the diseases, but no theory for the abdominal changes which are proved to exist. If these anatomical conditions of the contents of abdomen are not congenital they must be produced by some error or errors of management in childhood.

I revert now to the good lady who was so indignant with me in the out-patient department of the hospital. She insisted that the proper diet for a child was "a bit of what we have ourselves." I, in my superior wisdom, told her that the only diet for a child of 8 months was milk, which was to be continued until the child was 9 months old, and that after that time farinaceous food was to be gradually added to the milk, which was not to be decreased in quantity. Hence her contempt for me! Now in watching children grow and develop during the many years I have been in practice I have been struck with the little importance that seems to be placed on diet, so long as it is "digestible and nourishing"; these are the only two epithets ever applied to food, and what is meant by "digestible" is that there must be no overt act of indigestion, such as pain or wind. The more the child can eat of this kind of diet and the fatter it grows the more pleasure is given to the parents. The child may, and often does, require a "dose," but that is "only what all children want," and nothing is ever thought of it. An ordinary child starts the day with a breakfast consisting of bread and butter, an egg or some fish, and half pint of milk; in the middle of the morning it is given half pint of milk and some food of some sort—biscuits, rusk or bread; at from 1 to 1.30 it has a full meal of meat or fish, vegetables, and a pudding, generally a milky one; at 4.30 it has a good tea meal with jam to stimulate its jaded appetite, and half pint of milk; and at bed time it has another small meal. Altogether the child takes five meals daily, and no mother is satisfied unless it drinks at least two pints of milk in addition, and very often sweets are given as extras—I mean sweets of which sugar is the principal ingredient. All this food is of the digestible sort—i.e., all elements of it which are considered to be indigestible are carefully eliminated either by the nurse or mother. Now it must be confessed that the great majority of children pass through this period of their lives successfully, and no matter what they eat, or how much, they seem to keep well and remain free from disease. But certain of them fall by the way, and of these a good many are sufferers from dyspeptic troubles, loss of appetite, pain in the stomach, and flatulence. In many of these cases it is very easy to follow cause and effect, and if the diet, and especially the number of meals, is reduced improvement rapidly follows. A typical case is the following:—

P. A., aged 4½, was brought to me in October of last year. He had never been satisfactory; his appetite was bad, he suffered from abdominal pains, he was "anæmic," he slept badly, and was very easily tired. His bowels acted daily, but his motions were small, and sometimes there was a little "mucus" in them. *He had been to many doctors*, who could find nothing physically wrong, had ordered him tonics, and told his mother to feed him up. He was a bright, intelligent little fellow, very pale but not anæmic, and I could find no physical change except a distended tumid abdomen. *I told his mother to stop two of his meals daily*, and to substitute fruit and vegetables for most of his farinaceous food, and only to give milk as a condiment. The improvement was miraculous, and he lost all his symptoms for two months, when he suffered a slight relapse owing to constipation returning in the very cold spell of weather which we experienced in December.

Now I believe that this lad is in the early stage of abdominal change, and that he will be easily cured by the recognition of his condition. He was suffering from overfeeding and unsuitable feeding, which I believe to be the case with the majority of present-day children, and that, furthermore, it is the cause of the changes that are described.

In order to avoid the results it will be necessary to make considerable changes in the method of feeding children for the future. First of all, there must be a diminution in the number of meals, the most that may be allowed being three in the day. This allows time for one meal to be digested before another is poured into the stomach. The latter organ is thus not overfilled, and does not tend to become distended, the food is properly digested and passed on to the intestine in a fit condition for the further processes of digestion, and no overloading will take place. Then there must be great alterations of the food itself. As I have said before, all the mother asks of food at the present time is that it shall have three qualities—digestibility, nutritiousness, and *quantity*. *No thought* is taken as to the time that this diet will take in its passage through the digestive canal, and constipation is not looked upon as indigestion. It is as a rule easily corrected by a dose of medicine, and therefore of little importance. Now what is the most important acquisite of food? I unhesitatingly say its power of rapidly passing through the intestinal canal. *If food passes in* the proper time through these organs well and good. No matter what its quality or what its quantity no harm accrues, but if from any reason it lags by the way trouble begins. This is true stasis. Now this happens in our modern dietary, because all the laxative properties of food are carefully kept away from the child, as they are contained in that part of it which is usually called indigestible. The peels of potatoes, of apples, and other fruits, the stalks of cabbage and cauliflowers, the husks of all grain, are the necessary ingredients for stimulating the bowel to act, and they are carefully withheld from children, as they contain no nourishment and are "indigestible." Few children are allowed to eat raw fruit for the same reason, and consequently we see the results—stasis and its after-effects. Too much milk, too much straining after "nourishment," too many patent "pap" foods, are the reigning desiderata at the present time, whereas nature is quite able to pick out from even a scanty diet sufficient nourishment for the development of most children, if it is allowed to go its own way, undisturbed by tonics, digestives, and "doses."—I am, Sir, yours faithfully,

Buckingham-gate, S.W., Jan. 16th, 1921. H. A. DES VŒUX.

ORAL SEPSIS,

WITH SPECIAL REFERENCE TO CHRONIC DENTAL APICAL INFECTION.

To the Editor of THE LANCET.

SIR,—The interesting paper by Dr. W. Bertram Watson on this subject in your issue of Jan. 1st drew attention to a special feature of oral sepsis which is, in my experience, too often overlooked by dental surgeons and medical practitioners. I refer to a chronic dental infection, often round the apex of the root, where the gums and teeth are, as far as can be judged from careful macroscopical examination, perfectly healthy, and where no tenderness or pain are experienced by the patient. Too often in these cases the healthy appearance of the teeth has caused them, or rather the bony cavities containing them, to be disregarded as possible foci of serious infection without further examination. *It cannot be too strongly urged* that in all cases where the symptoms may be due to a chronic septic infection of unknown origin the jaw can only be excluded as a causal factor after a careful X ray examination has been made, and this should be *done however healthy the appearance of the gums* and teeth. It is remarkable how frequently cases of fibrositis, arthritis, and similar chronic conditions are met with in which, though the gums and teeth appear *perfectly healthy*, an X ray examination discloses definite septic foci round the apices of the teeth.

At the recent pathological meeting of the Medical Society of London on Jan. 10th, Sir William Hale-White and myself referred to a case of malignant endocarditis where the source of the infection was directly traceable to a septic focus round the apex of the left lower central incisor tooth. In this case an X ray examination by Mr. C. A. Clark revealed a small abscess, though to ocular examination the gums and teeth appeared perfectly healthy. I am strongly of opinion that oral sepsis is one of the most important causes of gastric and duodenal ulcer and that the septic absorption of pathogenic streptococci often takes place through the blood stream, the gums and teeth appearing externally healthy. There is considerable experimental evidence by Rosenow and others to confirm this view. Certainly, however healthy may be the appearance of the gums, an X ray examination of the teeth should be made in every suspected case of peptic ulcer.

I am, Sir, yours faithfully,

W. H. WILLCOX.

Welbeck-street, Cavendish-square, W., Jan. 24th, 1921.

MALARIA IN THE EAST AFRICAN CAMPAIGN.

To the Editor of THE LANCET.

SIR,—Little has been published respecting the medical aspects of the campaign in East Africa, and the papers of Majors J. P. Johnson and K. Gilchrist[1] and of Majors Johnson and Gilchrist and E. Hay-Michel[2] are a welcome contribution of the greatest interest and importance. After clinical and laboratory experience in various hospitals in G.E.A. during 1916–1919 I should like to endorse many of their findings. In 1000 blood smears, most of them thick drops, I had 40 per cent. positive, of which 71 per cent., B. tertian; 26 per cent., subtertian; 3 per cent., mixed B.T. and S.T.; under 1 per cent., quartan. They made no mention of quartan infections; at Morogoro I saw two cases in natives and only one case in a white man, so that possibly none were invalided to South Africa. Their figures naturally show a higher proportion of mixed infections, as these were more refractory to treatment and were therefore more liable to be invalided to South Africa. Higher dosage of quinine became the rule in the last one and a half years of the campaign, though medical officers new to the country often began with small "tonic" doses. In some hospitals a dosage of 60 gr. per diem was not uncommon. In my own cases I obtained better results with three-hourly doses of 10 gr. given as early in an attack as possible to a maximum of 30–40 gr. When an attack had been missed we endeavoured to produce mild tinnitus before the next rigor was due. In fact, the presence of tinnitus aurium was taken as a rough test of the absorption of quinine into the system.[3] In the subtertian type of infection with continued fever it is important that repeated small doses should be given throughout the night as well as the day to a maximum of 45 gr. in 24 hours. I often thought that the omission of quinine between 6 P.M. and 8 A.M. accounted for the fact that medical officers could not control these cases with oral quinine. Majors Johnson and Gilchrist rightly lay great stress on the presence of parasitological as well as of clinical relapses. Unfortunately, "bed-space" was the deciding factor in hospitals in G.E.A., and it was late in the campaign before convalescent camps (Dodoma and Nakuru) had the benefit of a laboratory. The paper is a striking demonstration of the fact that only by repeated blood examination can one judge of the effects of our treatment, a matter which has been too often disregarded in weighing the merits of different drugs and modes of administration. The relapse of 14 per cent. of previous "negatives" is not higher than one would expect. The promotion of the general powers of resistance of the body is duly appreciated by Majors Johnson and Gilchrist. During the years 1917–1918 how futile were our drugs against the effects of climate and the debility of our patients, and how striking the difference made by evacuation to Nairobi, Kijabe, and Nakuru (4000 feet).

As regards treatment with "606" I can testify to the beneficial effect in malarial cachexia and in the convalescent stage of blackwater fever. Captain D. S. Harvey, of the 15th Stationary Hospital, and later myself, used it (intramuscularly) in several cases, and Dr. R. W. Burkitt, of Nairobi, B.E.A., has elsewhere published his good results in civil cases. The action of arsenic as a stimulant to the hæmopoietic system is to cause a better type of red cell to be passed into currency, the spleen has thus less destructive work to do, gets rid of its débris and hence becomes smaller. I believe that the shrinking of the spleen is as much due to this as to any diminished activity of malarial parasites. I cannot help thinking that the effects on the liver which they ascribe to arsenic are chiefly due to the catharsis and light diet. In our V.D. section it was not unusual for an attack of malaria to occur within 48 hours after injection of "606," and in the few cases of malaria in which I tried "606" alone had eventually to be given quinine. I am, therefore, most sceptical about the parasiticidal action of arsenic in malaria. The great lesson of their paper is that chronic malaria in debilitated subjects can be overcome only by adequate quininisation, combined with general tonic measures and that constant blood examination is necessary to control the treatment.

I am, Sir, yours faithfully,

W. S. DAWSON, M.B., M.R.C.P.,

Hanwell, Jan. 16th, 1920.

INSURANCE MEDICAL RECORDS.

To the Editor of THE LANCET.

SIR,—At this juncture the leading article in your issue of Jan. 8th serves a very useful purpose. Just such a reasoned and sane pronouncement is much needed, for the numerous meetings held to discuss the record cards have been marked by much unwisdom in speech and resolution. Had these proceedings taken place in camera it would have been deplorable enough, but, unfortunately, in most instances the presence of pressmen has been courted, and their reports, as presented in the various papers, partake either of the nature of political propaganda or light comedy, and do little to uphold the dignity or intelligence of the medical profession.

At the very outset of the insurance agitation years ago Mr. Lloyd George was reported to have said: "Remember, National Insurance is not merely a doctor's endowment society," and we should do well to keep this pronouncement in mind. We may take what is called "panel practice" to be the germ, or foundation, of what it is hoped will one day grow into an efficient State Medical Service. Even now panel doctors are State servants holding a Government contract with definite conditions, of which record keeping is one. As State servants we have no concern with political or other like considerations. Our duty is to loyally carry out the terms of the contract we have accepted. Undoubtedly the record cards present features open to discussion, but they are sound in principle, a step in the right direction, and a great advance on the previous card system. If we approach the health authorities in a reasonable spirit, in time improvements will doubtless be made, but there is little in the present agitation to encourage the Department to give us a patient hearing. Is it reasonable to claim that the medical any more than any other profession is entirely faultless? There are doctors who *do*, and doctors who *do not*, take their panel practice seriously, and probably for *all* of us, and certainly for the latter, it is a good thing that we should have, in the record cards, to give an account of our stewardship.

I am, Sir, yours faithfully,

Havant, Jan. 22nd, 1921. ARTHUR J. GEDGE.

PART-TIME OR WHOLE-TIME FOR THE M.O.H. AND S.M.O.

To the Editor of THE LANCET.

SIR,—The pros and cons of part- and whole-time service for the medical officer of health and the school medical officer, though much discussed, are still under discussion.

Special arguments may be put forward upon the subject. It appears that the whole-time appointments are often sought after by members of the profession who shrink from the responsibilities and competition of general and special medical and surgical practice, because of its hard work and the ever-increasing knowledge and skill required in order to be efficient. The whole-time medical officer cannot be said to be a man of the most enterprising and energetic ideals in the practice of his profession. The late Local Government Board and the present Ministry of Health argue that the whole-time medical officer of health can more efficiently perform his duties as he is not directly interested in individuals and has in consequence an open and free hand to work with, and so it has become the custom to form combinations of sanitary authorities in rural districts for the purpose of appointing a whole-time medical officer of health, and in large towns the medical officer is also appointed upon the same terms and for the same reasons. This, then, is the chief argument for these appointments, but may it not be equally argued that the medical officer, who is a part-time officer, has a greater influence upon the residents of his district, and therefore can get more reforms carried out upon an intimation notice? This is my experience after nine years as a part-time medical officer of health.

Unfortunately the whole-time medical officer in many rural districts is much handicapped by distance and, I know, cannot carry out his duties as they should be; and, again, he is much more under the thumb of his council than the part-time medical officer. He has no sound security of tenure, whereas the part-time medical officer has not got all his eggs in one basket; he, therefore, for this reason has a much freer hand for action. Alike may be said in some degree of the whole-time school medical officer. It is a matter of regret to see the young medical men only recently qualified taking up these appointments, as it shows a want of enterprise and desire to maintain an up-to-date knowledge of their profession. It appears the young medico of to-day in many cases desires to obtain a job with as little work as possible; these appointments present themselves admirably in this respect.

The school medical officer himself, though usually the medical officer of health to the county council or county borough council, does not appear to do much medical inspection himself, but hands it over to a whole string of young assistants, who may be described as "birds of passage," and in many instances he does not even know the location of the schools in his area except on paper; much less does he visit them and take his share in medical inspection. Is he above this?

Now, the assistant school medical officer cannot do a reasonable 12 months' work in the year, as he can only work about 38 weeks in the year on account of the holidays. Nor can he work more than five days a week, as Saturday is a non-school day, and he can only work four hours a day or at the most four and a half hours. He cannot start before 10 A.M. on account of "call-over" and religious instruction, and he ceases at 12 noon, two hours dinner, and commences again at 2 P.M. and ends up at 4 P.M. Much of this work is very shoddily done, and appears but to consist of examination, as is the custom in an out-patients' department of a hospital, and often is completed by the scientific diagnosis of enlarged tonsils and adenoids or of defective sight. It might be asked whether a teacher or nurse could not discover a mouth-breather and carry out "Snellen's eye test" as well as a doctor. The thousands of pounds that are to-day paid in these school medical officers' salaries out of the county and borough rates mainly, in my opinion, are not justified unless the results of the work for which they are paid are more satisfactory than appear to be generally the case.

In support of these statements, which may appear pessimistic at first sight, one has only to read the general text of the Interim Report of the Consultative Council of Medical and Allied Services of May, 1920; and it is gathered that these remarks of mine were foreseen by the members of this most excellent Council to a great extent, inasmuch as the general medical practitioner is recognised as the backbone of the profession and of the health and welfare of the country, as is especially mentioned on pages 8 and 10 of the Report:—

> §24. The general practitioner, if adequately trained, should play a valuable part in the work of the communal services—e.g., antenatal supervision, child welfare, both before and during school age, physical culture, tuberculosis, venereal disease. He will be the first link in any chain of services to improve the conditions of industry, and to prevent any unfavourable or injurious influence upon the health of the workers.

> §39. *Communal services.*—There would be accommodation for communal services such as those for pre-natal care, child welfare, medical inspection and treatment of school children, physical culture, examination of suspected cases of tuberculosis and occupational diseases, &c. These services should, where possible, be aggregated at the primary centre.

It may be gathered from this report that the death day of the whole-time medical officer is not far ahead and most of the work they have been doing for the past ten years or so will pass into the hands of the general practitioner.—I am, Sir, yours faithfully,

A. M. BARFORD, M.D., F.R.C.S., D.P.H.

Chichester, Jan. 24th, 1921.

SUBNORMAL WORKERS AND INDUSTRIAL FATIGUE.

To the Editor of THE LANCET.

SIR,—Among many implications of Dr. C. S. Myers's interesting lecture on Industrial Fatigue, summarised in your last issue, are those that belong to the vocations and conditions of work of men, physically or mentally injured in the war. There is a large class of these men in the country, to which for want of a better word I have applied the term "reduced" or "subnormal" workers—in the sense that they are unfit for ordinary conditions of industry. It is surely time that the guiding principles which emerge from the researches described by Dr. Myers were applied in the daily work not only of "normal" (soi-disant) but "subnormal" men. After some little study of this special category of workers, suffering from many different kinds of more or less permanent disablement, I should like to suggest three points, in confirmation or modification of Dr. Myers's conclusion.

1. Many subnormal become not simply fatigued but exhausted by work, which must, especially at first, be carefully graded to the abnormal fatigability of each individual. This is especially true after nervous shock, in which the will to work often exceeds the power, and, as Dr. Myers says, the inhibition of nervous expenditure is itself inhibited. It is very necessary to go slow with these people, and "ca' canny" not in production but in effort.

2. The importance of *variety* in work is illustrated continually. It is, for example, essential that the subnormal worker on the land must have "supplementary industries," and divide his time between the field and home work. The case of girl operatives in the boot and shoe industry is cited, where 20 minutes' rest in each hour largely increased the output. For many others a change of occupation is equally refreshing and beneficial.

3. We are told that "willingness to become an automaton" is getting rarer. Among my subnormal friends it is, I think, happily extinct. Work for them must be interesting. I asked a nerve-shocked man if he thought men like himself could and would work four hours a day. His answer was: "Certainly, provided they could look upon it as a hobby."

I am, Sir, yours faithfully,

Devonshire-place, W., Jan. 25th, 1921. R. FORTESCUE FOX.

COLITIS IN PNEUMONIA.

To the Editor of THE LANCET.

SIR,—I venture to support Sir W. Hale-White's opinion (THE LANCET, Jan. 22nd, p. 200) that acute colitis is very rare in lobar pneumonia by my own experience of one example only in 558 consecutive cases. I regret that I have no details now to hand of the intestinal symptoms beyond the facts that they appeared during the patient's treatment in hospital and that recovery took place. In three of my cases gastro-intestinal disturbance of some kind or other was the presenting symptom, and with Sir W. Hale-White's letter before me I am vividly reminded of one of these, a man aged 38, who upon the usual interrogation at his admission into the ward said: "For two days I have been suffering with the bloody flux." (He was, I think, a student of old English literature.) This patient had a temperature of 103·6° F. without physical signs of any description beyond the passage of comparatively fresh blood by the bowel. I confess that the possibility of pneumonia did not occur to me, but, exactly as in Sir W. Hale-White's case, within a short time unequivocal signs of consolidation with rusty sputum developed.

Sir W. Hale-White's letter was prompted by an article in your issue of Jan. 15th by Dr. E. Cronin Lowe upon three cases of influenzal pneumonia. In this Dr. Lowe refers to a publication by my colleagues, Dr. Herbert French and Dr. N. F. Hallows, and myself, and says that although we mention the normality of the appendix and bowel generally in our autopsies we do not definitely state whether the bowel was examined in detail throughout. We mentioned the appendix specifically in view of the statements that had appeared that there was a tendency for influenzo-pneumonic patients to develop acute appendicitis and so to emphasise that such was not the case in our experience. As for the alimentary canal as a whole we were satisfied to state that it exhibited no particular change, and I may now add that the whole length was examined critically by Dr. French, which is a guarantee of thorough investigation and of accurate pathological interpretation, in a large proportion of our earlier autopsies, a procedure subsequently neglected in view of the persistently negative findings. This, of course, does not eliminate the possibility of cases with ulceration or necrosis of the bowel having actually occurred and which would have been detected if systematically investigated for, as Dr. Lowe says, the peritoneum gives no evidence of such inflammatory change in the bowel itself. But when one recalls the remarkable seasonal and local peculiarities exhibited by crops of influenzo-septicæmic cases I think it more likely that Dr. Lowe's cases were of a special type.—I am, Sir, yours faithfully,

ADOLPHE ABRAHAMS.

Park-crescent, Portland-place, W., Jan. 25th, 1921.

BILHARZIA-INFESTED SNAILS AND THEIR EMPLOYMENT AS ANTIGEN.

To the Editor of THE LANCET.

SIR,—Although the dams along the course of the rivers of Natal and the many stagnant pools that are produced by the floods swarm with fresh-water snails and other evidences of stream-pollution, the collecting of sufficient numbers of the various species which harbour parasites requires much patient search, and a great deal of success depends upon the state of the weather and wind. At this season of the year about 1 in 6 *Physopsis africana* are infested with schistosomes. Only a small proportion of infested specimens harbour the parasite which causes bilharzia disease in man, a greater number being infested with cercariæ which develop into *Schistosoma bovis*. I have found schistosomes developing in *Isidora tropica*, *Isidora forskali*, *Isidora schackoi jickeli*, *Physopsis africana*, *Limnæa natalensis*, and *Planorbis pfeifferi*, but have not yet secured the adult forms of any besides *S. hæmatobium* and *S. bovis*.

Dr. W. A. Murray has prepared a very efficient antigen from the livers of *Physopsis africana*, which harbour these schistosomes. This has involved the dissection of a large number of specimens; for at least 15 gr. of infested liver-substance is needed in the preparation of the antigen for the complement-fixation test. But livers harbouring the cercariæ of *S. bovis* appear to be just as useful as those infested with the cercariæ of *S. hæmatobium*. Besides giving a positive reaction in patients who harbour the more common bilharzia parasites, the test has given a positive reaction in a patient from China, whose fæces contain the typical unspined eggs of *S. japonicum*. This blood-test, introduced by Dr. Hamilton Fairley, promises to be of even greater value in the diagnosis of *Schistosomum bovis*. The spindle-shaped eggs that I have seen in guinea-pigs experimentally infested with this parasite are on an average 0·175 by 0·04375 mm. in diameter. These parasites do not appear to cause as much bleeding as is common in persons infested with *S. hæmatobium*, and the diagnosis of their presence in cattle and the effect of appropriate treatment will be decided very largely by the reaction of the serums to the antigen test.

On Oct. 19th I asked Dr. Murray to apply the test to the serums of seven sheep that are known to harbour liver-flukes and are now undergoing a course of injections for this complaint; a positive reaction was obtained in each case. An antigen prepared from fresh-water snails infested with schistosomes may, therefore, be used in the diagnosis of bilharzia and fasciola disease in man and beast.

I am, Sir, yours faithfully,

F. G. CAWSTON, M.D. Cantab.,
First Streatfeild Research Scholar.

Durban, S. Africa, Nov. 15th, 1920.

A SIMPLE METHOD OF GROWING THE ACNE BACILLUS.

To the Editor of THE LANCET.

SIR,—Having experienced some difficulty in separating the acne bacillus from the staphylococci which usually accompany it in comedoes and acne lesions by such methods as are known to me, the following procedure has been found to afford an easy means of effecting the separation and of growing the bacillus without trouble.

The medium consists of ordinary peptone broth to which is added 1 per cent. of oleic acid and 1 per cent. of glucose. About 10 c.cm. of the medium is distributed in each tube, and a layer of melted vaseline is run on the surface of the broth. The tubes are then sterilised. A suspension of a comedo crushed in a little normal salt is introduced with a pipette into the medium. The opening thus made in the vaseline is sealed by the application of heat so as to render the cultures anaerobic. After incubating the inoculated tube at 37° C. for four days large numbers of acne bacilli will be found to be present. At this date, in such an environment, the acne bacilli usually outnumber the staphylococci, the growth of which appears to be restrained, and a pure culture is readily obtainable in the usual manner. By concentration of the growth by centrifugalisation from a number of such anaerobic cultures acne bacilli can be obtained in considerable quantities.

W. E. DE KORTE, M.B. Lond.

Cape Town, Nov. 17th, 1920.

MITES AS INTERNAL PARASITES IN MAN.

To the Editor of THE LANCET.

SIR,—*Re* the occurrence of mites as internal parasites in man, discussed at the last meeting of the Medical Society of London and reported in THE LANCET of Jan. 22nd (p. 175), it is interesting to note an article by Mr. R. J. Pye-Smith[1] in which it is stated that he drew off in July, 1899, fluid from a testicular cyst of a patient who some years previously had spent a short time in India, and whilst there had been catheterised for retention of urine in an attack of fever. This fluid was examined by Dr. C. Munro Hector, who found numerous living acari, shed skins, and ova. Unable to identify them, Dr. Hector consulted Mr. A. Denny, F.L.S., who advised him to send the specimen to Mr. A. D. Michael, F.Z.S., then the foremost British authority on acari. Mr. Michael was too busy to undertake this investigation, which he passed on to Dr. E. Trouessart, of Paris, who published the result.[2] Dr. Trouessart wrote:—

---

[1] Quarterly Medical Journal, August, 1902, p. 323.

> "I was convinced that it was a sarcoptide, of the sub-family Tyroglyphinæ (*Sarcoptides détriticoles*), nearly related to the *Histiogaster carpio*, Kramer, but a new variety, which I propose to call *Histiogaster spermaticus*, to recall the exceptional circumstances under which this species has been discovered."

Trouessart was surprised to find a species new to him, and concluded that it belonged to the fauna of India and had been introduced at the catheterisation mentioned above. The male and female are both illustrated in Trouessart's account, and this illustration is copied in Pye-Smith's account.

I am, Sir, yours faithfully,
Buxton, Derbyshire, Jan. 21st, 1921. C. SUFFERN.

TABES: ITS EARLY RECOGNITION.

To the Editor of THE LANCET.

SIR,—The letters of Dr. E. F. Buzzard and Dr. E. T. Burke show that I have failed to make the first premise of my argument clear. That argument amounts to: A syphilitic starts treatment while the blood is still negative; he receives 2·6 gr. of "606" and 8 g. of mercury; the disease is eradicated. I have asked for any rare exceptions to the rule to be accurately defined, where the above propositions have been indubitably fulfilled. The first of these two conditions upon which I base my conclusion does not include all cases of primary syphilis, as we know it clinically—far from it. Let us call them Class A. In July, 1919, I checked the case cards of 400 consecutive cases. Actually less than one-third could be placed in Class A. The other much larger class amply accounts for the sad sequence of events emphasised by Dr. Buzzard and Dr. Burke, and as far as that unfortunate class is concerned I naturally agree with all that they have said.

I am, Sir, yours faithfully,
Leicester, Jan. 23rd, 1921. JOHN DONALD.

THE TREATMENT OF PAUPER LUNATICS.

To the Editor of THE LANCET.

SIR,—In this week's issue of the *Medical Press and Circular* appears the first of three articles headed Asylum and Lunacy Law Reform. It is with regret one reads the statements made, in a paper presumably edited by a medical man—e.g., "In these wards (asylum) and airing courts one sees a motley group of lunatics ...... indiscriminately herded together without any attempt at classification and segregation ...... living together in the closest contact and intimacy under the care of male and female attendants, themselves ill-trained, underpaid, and underfed, and for the most part callous and indifferent to the welfare of those of whom they are in charge." Again, "the patients are deprived of their own clothes, clad in a distinctive and humiliating garb, ill-shod, unkempt, often insufficiently protected against the weather, fed on monotonous, innutritious, badly cooked, and repulsively served food," and so on in the same strain.

The writer evidently has not read the reports of the Commissioners of the Board of Control, nor is he aware of the careful and advanced training undergone by male and female mental nurses, necessary to obtain the nursing certificate of the Medico-Psychological Association. These statements may be copied by the lay press and obtain a certain amount of credence by persons as ignorant as the writer of the actual conditions which exist in county mental hospitals, both as regards the treatment of mental cases and the administration of such institutions.

I am, Sir, yours faithfully,
J. B. TIGHE,
Medical Superintendent, Gateshead County Borough
Mental Hospital, Stannington, Northumberland.
Jan. 21st, 1921.

TUBERCULOUS MILK.

To the Editor of THE LANCET.

SIR,—Recent correspondence in the professional journals has revealed considerable diversity of opinion regarding the infectivity of bovine tuberculosis to man. At the last meeting of the council of the Society of Medical Officers of Health representations on the subject were received from the Tuberculosis Group and individual members of the society, and the following resolutions were adopted unanimously:—

> (*a*) That in the opinion of this society it has been conclusively proved that bovine tuberculosis is transmissible to children through the ingestion of infected milk.
> (*b*) That this society regards the evidence of immunisation by the ingestion of living tubercle bacilli in milk as entirely unproved.

I was directed to forward you a copy of these resolutions for the information of your readers.

I am, Sir, yours faithfully,
G. S. ELLISTON,
Executive Secretary, Society of Medical Officers of Health.
1, Upper Montague-street, W.C., Jan. 22nd 1921.

THE CRIPPLING DISABILITIES OF CHILDREN.

To the Editor of THE LANCET.

SIR,—In Mr. G. R. Girdlestone's scheme (THE LANCET, Jan. 8th, p. 74) for thorough treatment of crippled children there is an additional advantage which he leaves unmentioned. A nation-wide series of orthopædic hospitals, with staffs experienced in the best treatment of all sorts of deformities, with methods and appliances constantly improving, will provide from the beginning of the next war many surgeons and many asylums to care for disabled soldiers to the very best advantage, so that the largest proportion possible may come back to industrial efficiency. We have been able to get much done in this war, more than we could have believed, but it took time before this work was given to the orthopædic surgeons, before they had shown us how useful to the wounded their specialty could be. That time will be saved to the wounded in the next war if Mr. Girdlestone's proposals become effective.

I am, Sir, yours faithfully,
Jan. 22nd, 1921. MILES.

Obituary.

RUPERT FARRANT, *M.C.*, F.R.C.S.ENG.

THE tragic death, at the early age of 37, of Mr. Rupert Farrant, until recently assistant surgeon and lecturer in practical surgery and endocrinology at Westminster Hospital, has been widely reported in the press. The youngest son of the late Mr. Samuel Farrant, of Taunton, Somerset, Rupert Farrant had a distinguished career as a student at Westminster and St. Bartholomew's Medical Schools. He qualified M.R.C.S.Eng., L.R.C.P. Lond., in 1906, becoming F.R.C.S. in 1909. Mr. Farrant made a special study of the influence of the thyroid gland on general metabolism, and it was on this subject that he delivered lectures at the Royal College of Surgeons of England as Hunterian Professor on two occasions. The name of Rupert Farrant must be added to the not inconsiderable list of distinguished officers who broke down after the strain of arduous war service, often, as in his case, after having received a decoration testifying to especial gallantry.

ROYAL CORNWALL INFIRMARY, TRURO. — The annual meeting of the subscribers of the Royal Cornwall Infirmary was held recently. The accounts showed a considerable deficiency, and it was resolved that every patient who could do so should make a contribution towards the cost of maintenance. £15,000 are required for the building and renovation of the institution, and towards this sum £10,000 have already been raised.

Medical News.

UNIVERSITY OF OXFORD: LECTURES IN CLINICAL MEDICINE AND SURGERY.—Sir Archibald Garrod, the Regius professor of medicine, is conducting a course of clinical lectures on Tuesdays, at 2.30 P.M., at the Radcliffe Infirmary. Clinical lectures are also being given by Dr. W. Collier, the Litchfield lecturer in medicine, and by Mr. A. P. Dodds-Parker, the Litchfield lecturer in surgery.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—The following Hunterian lectures will be delivered in the theatre of the College at 5 P.M. On Monday, Jan. 31st, Professor W. Sampson Handley will lecture on the Pathology and Surgery of Lupus. On Wednesday, Feb. 2nd, Professor Walter G. Howarth will lecture on Mucocele and Pyocele of the Nasal Accessory Sinuses. On Friday, Feb. 4th, Professor C. W. Gordon Bryan will lecture on Injuries of the Diaphragm, with Special Reference to Wounds Jointly Involving Thoracic and Abdominal Viscera.

FEDERATION OF MEDICAL AND ALLIED SOCIETIES.—At a meeting of the Executive Council, held at 11, Chandos-street, London, W., on Jan. 25th, the following societies were elected to membership of the Federation: The Harrogate Medical Society, the Infirmary Medical Superintendents' Society, and the Chartered Society of Massage and Medical Gymnastics.

ROYAL SANITARY INSTITUTE.—An introductory lecture to students attending the several courses of instruction at this institute, 90, Buckingham Palace-road, London, S.W., will be given by Professor H. R. Kenwood on Jan. 31st at 5.30 P.M.

A DINNER "to celebrate the admission of women to the Chemical Society" will be held at the Lyceum Club under the auspices of its University Board on Monday, Jan. 31st, at 8 P.M. Dr. Smedley Maclean will preside.

ROYAL LONDON OPHTHALMIC HOSPITAL.—The annual dinner of past and present students will be held at the Café Royal, Regent-street, on Thursday, Feb. 10th, at 7 for 7.30 o'clock. The chairman will be Mr. J. B. Lawford, consulting surgeon to the hospital. Tickets, at 15*s.* (excluding wine), should be obtained as soon as possible from Mr. Charles Goulden, 42, Welbeck-street, London, W. 1.

ONODI COLLECTION OF NASAL ANATOMY.—As has been announced in THE LANCET the gift of the Onodi Committee of the valuable collection of nasal anatomy has been accepted by the Royal College of Surgeons of England. The College have undertaken to mount and catalogue the specimens, and when completed will present a copy of the catalogue to each subscriber. The following is the list of subscribers up to date:—

	£	*s.*	*d.*

Mr. Philip Franklin, 27, Wimpole-street, is acting as honorary secretary and treasurer of the movement.

ROYAL INSTITUTION OF GREAT BRITAIN.—The Friday Evening Discourse on Feb. 4th will be delivered at 9 o'clock by Professor A. D. Waller, F.R.S., on the Electrical Expression of Human Emotion.

UNIVERSITY OF VIENNA.—The Dean of the Medical Faculty announces a concentrated post-graduate course to be held from Feb. 7th to 19th. Lectures and demonstrations will be given from 9 to 12 and from 2 to 6 daily. Cardiac Conditions will form the subject dealt with on Feb. 7th and 8th, and will be discussed by Professor K. F. Wenckebach, Professor H. Winterberg, Professor H. Eppinger, Hofrat Professor Jakob Pal, Regierungsrat Professor M. Sternberg, Professor O. Stoerk, and Professor H. H. Meyer. Foreign medical men are invited to apply to the Publisher of the *Wiener Medizinischen Wochenschrift*, 22, Porzellangasse, Vienna IX., for further information. The fee for the course is 1000 kronen for foreigners. Further courses will be held in June, September, and December, 1921.

THE COLLEGE OF NURSING.—A few months ago it was announced that Viscount and Viscountess Cowdray had purchased 20, Cavendish-square, W., and presented it to the College of Nursing for its headquarters, and for a residential club for College members. A 999 years' lease has since been acquired from the Howard de Walden Estate. The Council of the College now recommends that the house shall be exclusively used as a club, and that the garden, having a frontage to Henrietta-street, shall be utilised as a site for the College. To give effect to this recommendation, Viscountess Cowdray has advised the Council that the gift will be increased to a total of £100,000. The conversion of the mansion into the club house will be taken in hand forthwith, and should be completed by midsummer. It is proposed to delay the erection of the College until building operations become cheaper. The College will contain offices, class-rooms, laboratories, lecture halls, &c., while the upper floors will provide over 50 bedrooms, having direct access to the club, which will be named the Cowdray Club.

STUDENTS' MEDICAL SOCIETIES.—We have received the following announcements of forthcoming meetings of medical societies attached to certain metropolitan medical schools:—

Charing Cross Hospital Medical Society.—At the meeting on Feb. 1st Mr. S. Fenwick will speak on Shooting. On Feb. 15th a paper on the Evolution of Some Descriptive Terms will be read by Professor E. Barclay-Smith. On March 1st Sir Frank Colyer will speak on the Comparative Anatomy of the Teeth. The meetings are held at 5 P.M.

King's College Hospital, Listerian Society.—The next meeting will be held on Feb. 2nd, when Dr. G. A. Harrison will read a paper on Functional Albuminuria. On Feb. 16th the Rev. K. E. D. Dauncey will speak on God and Disease, and on March 2nd Mr. G. de M. Rudolf on Animal Mythology of the Middle Ages. On March 16th a clinical evening will end this session's meetings, which are held at 8.15 P.M.

London Hospital Medical Society.—On Feb. 10th Dr. W. J. O'Donovan will speak on Alopecia. On Feb. 24th Dr. G. E. Vilvandré will read a paper on the X Ray Diagnosis of Some Gastric Diseases, and on March 10th Mr. Eardley Holland will speak. On March 17th Mr. W. S. Perrin will read a paper on Intussusception. The meetings begin at 8 P.M.

Middlesex Hospital Medical Society.—The next meeting will be held on Feb. 10th, when Mr. C. H. S. Webb will describe four cases. On Feb. 24th Dr. E. A. Cockayne will speak on Hermaphrodites and Intersexes in Insects, and Mr. W. N. Kingsbury will read a paper. On March 10th Dr. Tuck, D.Sc., will speak on "The Relationship between Chemical Constitution and Physiological Action," and Mr. C. P. Wilson will read a paper. Cases of clinical interest or pathological specimens are demonstrated at all meetings, which are held at 5.15 P.M.

St. Mary's Hospital Medical Society.—The next meeting will be held on Feb. 9th, when Sir Thomas Horder will speak on Doctors in the Making. On Feb. 23rd Sir Humphry Rolleston will speak on Diseases Described by their Medical Victims. On March 9th Professor Parsons will read a paper on the Skull of Modern Englishmen; and on March 16th Mr. W. Clayton-Greene will read a paper. The meetings are held at 8 P.M.

University College Hospital Medical Society.—The annual dance will be held on Feb. 7th (tickets at 15*s.* obtainable from Mr. W. G. Spencer-Cox, honorary secretary). On Feb. 9th Mr. Herbert Tilley will read a paper on Some Experiences. On March 9th Dr. C. Price-Jones will speak on Blood Pictures. On May 11th Dr. T. R. Elliott will read a paper on Gas Poisoning, and on June 8th Mr. Wilfrid Trotter will speak on Minor Injuries of the Brain. Clinical evenings will be held on Feb. 25th, March 21st, and May 23rd, at 8 P.M. Ordinary meetings are held at 8.15 P.M.

UNIVERSITY OF ABERDEEN.—At a special meeting of the University Court, held on Jan. 18th, it was agreed to be desirable that so far as possible the increase of fees in the Scottish universities should be uniform, and it was resolved to increase the inclusive fees in all the faculties. The scales of increase to be adopted were referred to a committee for consideration. The Court resolved that any increase of fees should not apply to students who had already commenced university courses prior to intimation being made by the University Court of the increase of fees.

PUBLIC HEALTH CONFERENCE IN ABERDEEN.—The Scottish Board of Health having asked various bodies to meet with Dr. J. C. McVail, one of the Board of Health officials, and Mr. Fraser, the secretary, a conference was held in the Aberdeen Town House on Jan. 19th. Councillor Doig, convener of the Public Health Committee of the Town Council, presided, and there were also present: Principal Sir George Adam Smith, Dr. J. Crombie, of Parkhill, and Major H. J. Butchart, D.S.O., secretary of the University, representing the University; Mr. D. M. M. Milligan, advocate, representing the Sick Children's Hospital; Mr. John Ellis and Mr. A. Scott Finnie, clerk and treasurer, representing the Aberdeen Royal Infirmary; and Professor Ashley W. Mackintosh and Dr. Lawson, representing the joint hospital scheme. Dr. J. Parlane Kinloch, deputy M.O.H., and Dr. George S. Banks, assistant medical officer for the city of Aberdeen, were also present. A general discussion took place on questions such as sanatorium benefit, the need for economy, and proposals in connexion with the proposed joint hospital scheme for Aberdeen. The views expressed will be reported to the various bodies by their representatives.

SCHEME OF MEDICAL SERVICE FOR SCOTLAND: A PROTEST.—The Medical Guild has issued a memorandum protesting against the scheme of medical service for Scotland put forward in the interim report of the Consultative Council on Medical and Allied Services, and especially to the proposal to extend National Health Insurance to dependents. In a circular letter addressed to members of the profession in Scotland signed by the President of the Medical Guild, Emeritus Professor F. M. Caird, and its honorary secretary, Dr. Frederick Porter, the recommendations in the interim report are summarised, and the report is described as an audacious attempt to foist upon the people an aggressively inquisitorial system. The letter continues: "The profession and the public can now see clearly what certain politicians have been aiming at ever since the passing of the Insurance Act—namely, the subordination of individual members of the profession to the will of an autocratic body, and the invasion of the privacy of family life by State officials." Recipients of the letter and memorandum are asked to state on a post-card whether they approve of the views expressed, or whether they approve of the proposed extension of National Health Insurance. It is added that their replies will be treated as confidential.

SURGICAL AID SOCIETY: PORTSMOUTH BRANCH.—The annual report, which was presented at a meeting held in the town hall on Jan. 20th, stated that 1069 surgical appliances had been supplied during the year. The subscriptions, with interest, amounted to £1269 8*s.* 11*d.*, as compared with £945 1*s.* 4*d.* in the preceding year. There was an excess of £331 13*s.* 10*d.* in expenditure over income which had been paid by the parent society. The Portsmouth branch is the second largest branch in the country.

UNIVERSITY OF MANCHESTER.—At the last meeting by the Council and Senate a resolution was passed expressing the deep regret of the Council and Senate at the resignation by Sir William Thorburn of his position as senior honorary surgeon to the Manchester Royal Infirmary, which involves also his resignation of the Chair of Clinical Surgery in the University. The Council and Senate expressed their high appreciation of his great services to the University, of his contributions to the advancement of surgery, and of his distinguished record and skill in the practice of his profession. The resolution further called attention to the devotion which he had brought to the administrative side of his University work, and the geniality and consideration with which he had treated his colleagues.

The total number of students attending the University during 1920–21 is 2788, as compared with 2549 in 1919–20, 1036 in 1918–19, and 871 in 1917–18. The numbers of new students admitted this session are 548 men and 201 women; last session the corresponding numbers were 941 and 188. 154 of these students come from countries other than England—21 from Egypt, 18 from India, and 10 from South Africa. Serbia has sent 5 students, Australia, Bulgaria, Palestine, Siam, U.S.A., and Switzerland 2 each.

The University prize in medicine has been awarded to Mr. L. J. Witts.

THE INCREASED COST OF DRUGS.—At the last meeting of the Truro (Cornwall) Board of Guardians a district medical officer applied for an increase of salary, and owing to the increased cost of drugs he asked the guardians in future to defray the cost of the drug bill. The guardians agreed to this proposition.

SANATORIUM FOR TUBERCULOSIS IN SOMERSET.—The Somerset County Council has purchased Quantock Lodge, which is to be adapted for the treatment of tuberculosis. The cost of the scheme will be £55,600. The more expensive scheme of erecting an institution at Lyncombe Hill has been abandoned.

BRITISH COMMITTEE FOR AIDING MEN OF LETTERS AND SCIENCE IN RUSSIA.—At the beginning of this year an appeal was published in THE LANCET (Jan. 8th), for funds to enable a certain number of scientific and literary publications to be sent to the House of Science and House of Literature in Petrograd, where the remnant of the intellectual life of Russia is mostly congregated. The British Committee for Aiding Men of Letters and Science in that country has assured itself that such publications will reach their destination, and has made arrangements for their transmission. There are probably many authors who would be willing to send copies of their works in the form of excerpts or otherwise to Russian workers who have been cut off from the outside world since the revolution. The British Committee will be glad to receive any such books or papers of a non-political type, and to send them to Petrograd. It cannot guarantee delivery to individuals, but it can ensure that publications will reach the Houses of Literature and Science. Parcels for transmission should be addressed to the Committee, care of Wm. Dawson and Sons, Ltd., Continental Dept., Rolls Building, Fetter-lane, E.C. Mr. L. F. Schuster is acting as secretary to the movement, and he may be addressed at the British Science Guild Offices, 6, John-street, Adelphi, London, W.C. 2.

ST. BRENDA'S PRIVATE HOSPITAL, BRISTOL.—This new hospital has recently been opened. It is situated in a pleasant and accessible neighbourhood near Clifton Down, and consists of two houses, which have been turned into one and adapted so as to furnish a hospital of about 40 beds, with small wards. The objects of the hospital are (*a*) to provide a private hospital where scientific investigation and treatment of disease may be obtained by those whose circumstances render this impossible save by admission to a charitable institution; and (*b*) to coöperate closely with the patient's own medical attendant. Under no circumstances will patients be admitted without letters of recommendation from their own medical attendants, who will be invited to assist in various ways in the care of the cases. The staff consists of two physicians, two surgeons, one gynæcologist, one ophthalmic surgeon, one rhinologist, one dermatologist, two anæsthetists, one skiagraphist, and one pathologist. All are members of the assistant staffs of the Royal Infirmary and General Hospital. The tariff of fees includes ordinary charges for maintenance and for medical attendance, and special charges for operations, for special investigations, and for confinements, and lie between the small sums now being collected by some of the voluntary hospitals and the larger fees paid by patients in the average nursing home.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.—At a meeting held on Jan. 6th Dr. Donald Hall showed a woman of 38 years, the subject of Left-sided Artificial Pneumothorax induced 12 months before for advanced pulmonary tuberculosis. She was doing well. Mr. H. F. Seymour read notes of a case of Wrist-drop treated by tendon transplantation. The patient, a woman of 45, had cut her left arm with glass, severing the posterior interosseous nerve, and when seen by him six months after the injury had complete paralysis and wasting of the corresponding muscles. He decided against nerve suture on account of the density of the scar tissue and the smallness of the posterior interosseous nerve, and transplanted the flexor carpi radialis obliquely into the extensor communis digitorum. The result had been excellent, within six weeks movements being very nearly normal except for highly skilled tasks such as piano playing. Mr. C. H. Bryant read a paper on the Effects of Errors of Refraction. He spoke of the three types of eye-fatigue: retinal, muscular, and mental. The sensitiveness of the individual was the chief determining factor in the production of symptoms rather than the amount of the defect. Mr. Bryant then discussed in some detail the pathology and symptoms of myopia, hypermetropia, and astigmatism. In astigmatics he considered that when symptoms supervened they were usually attributable to the mental strain of interpreting an indistinct picture. Dr. J. F. Gordon Dill addressed the meeting on the scheme of voluntary hospital insurance inaugurated by him.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lieuts. J. D. Bangay and L. F. Strugnell to be Surgeon Lieutenant-Commanders.

ARMY MEDICAL SERVICE.

Col. J. R. McMunn vacates the temporary appointment of Assistant Director-General.

ROYAL ARMY MEDICAL CORPS.

Lieut.-Col. J. Hennessy is placed on the half-pay list on account of ill-health.

Majors J. B. Meldon and R. B. Hole, and Capt. R. C. Robertson retire, receiving a gratuity.

Capt. J. E. Dunbar is restored to the establishment.

Temp. Capt. H. N. Webber relinquishes the acting rank of Major.

W. A. Byrn to be temporary Lieutenant.

Officers relinquishing their commissions:—Capt. H. C. Gilmore (retains the rank of Captain). Temporary Captains retaining the rank of Captain: J. N. Deacon and P. Templeton. Temp. Lieut. T. B. Bokenham (retains the rank of Lieutenant).

SPECIAL RESERVE OF OFFICERS.

Capt. C. H. Carlton relinquishes his commission on appointment to the R.A.M.C. (T.F.).

TERRITORIAL FORCE.

Lieut.-Col. C. S. Brebner resigns his commission and retains the rank of Lieutenant-Colonel.

Major J. B. Scott (late R.A.M.C., S.R.) to be Captain and to relinquish the rank of Major.

Capt. L. Ball to be Major.

Capt. E. F. Skinner (late R.A.M.C., T.F.) to be Captain.

Capt. J. Dale resigns his commission and is granted the rank of Major.

ROYAL AIR FORCE.

Capts. J. Fanning and J. P. Hosford are transferred to the Unemployed List.

INDIAN MEDICAL SERVICE.

The King has approved of the retirement of Col. T. Stodart.

DEATHS IN THE SERVICES.

Lieut.-Col. Henry Peers Dimmock, I.M.S. (retired), on Jan. 23rd, at his residence at Sydenham. He joined the Service in 1880 and was attached to the 2nd Baluch Regiment. While civil surgeon at Shikarpur he observed that the excessive gaol mortality in the prisons of Northern India was due to epidemic cerebrospinal fever. The complaint was then more closely investigated and there was substantial reduction of prison mortality. In 1891 he was appointed obstetric physician at the Jamsetjee Jeejeebhoy Hospital and professor of midwifery at Grant Medical College, subsequently principal of the college, and senior medical officer of the hospital. In 1897-98 he was appointed medical member of the Executive Plague Committee.

Appointments.

CATES, J., M.D. Lond., D.P.H. Camb., has been appointed County Medical Officer of Health for Surrey.

DAVIDSON, M., M.A., M.D. Oxon., Assistant Physician to the Brompton Hospital for Consumption and Diseases of the Chest.

EAST, A. G., M.B., B.Ch. Oxf., Honorary Ophthalmic Surgeon to the Royal Cornwall Infirmary, Truro.

REES, H. W. M., M.R.C.S., L.R.C.P., Medical Superintendent of the Training Centre for Out-door Occupations for Tuberculous ex-Service Men, Maidstone.

WALFORD, H. R. S., M.R.C.S., L.R.C.P., Senior Assistant Physician to Union of South Africa Mental Hospital Service.

WHITEWAY-WILKINSON, A. C. S., L.R.C.P., M.R.C.S., District Medical Officer and Public Vaccinator for Kingsteignton.

WILLWAY, C. V. D., M.B., Ch.B. Edin., Surgeon to Stroud Hospital.

Surgeons under the Factory and Workshop Acts: MACAULAY, J. G. M., L.R.C.P. & S. Edin., L.F.P.S. Glasg. (Inverary); RYAN, R. A., L.R.C.P. & S. Irel. (Ripley); DAVEY, S., L.R.C.P., M.R.C.S. Eng. (Caterham); EVANS, R. D., L.R.C.P. & S. Edin., L.F.P.S. Glasg. (Festiniog); PATERSON, W. L., L.R.C.P. & S. Edin., L.F.P.S. Glasg. (Kirkwall); TAYLOR, J. (Keith).

Vacancies.

For further information refer to the advertisement columns.

Altrincham General Hospital, Cheshire.—H.S. £175.

Birkenhead and Wirral Children's Hospital, Woodchurch-road.—H.S. £150.

Manchester Children's Hospital, Pendlebury, near Manchester.—Res. M.O. £150. Also Asst. S. £50.

Manchester Royal Infirmary.—H.S. to Special Departments. £50. Also Jun. Asst. £100.

Metropolitan Hospital, Kingsland-road, E.—Asst. P.

Newark Hospital and Dispensary.—Res. H.S. £200.

Newcastle-upon-Tyne, Hospital for Sick Children.—Hon. Asst. P.

Nottingham General Hospital.—H.P. £200.

Paddington Green Children's Hospital, London, W.—P. to Skin Dept. and P. to Out-patients.

Plymouth, South Devon and East Cornwall Hospital.—H.P. £150.

Queen Charlotte's Lying-in Hospital, Marylebone-road, N.W.—Obst. S.

Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Res. M.O. £200. H.S. £100. Also Ophth. S.

Queen Mary's Hospital for the East End, Stratford, E.—H.S. Also Hon. Ophth. S.

Reading, Royal Berkshire Hospital.—Second H.S. £200.

Royal Dental Hospital of London.—Asst. Dental S. Also Asst. Hon. Radiographer.

St. Mary's Hospital, Paddington, W.—Electro-therapeutic O.

Sheffield Royal Infirmary.—Asst. Cas. O. £150.

Singapore, Straits Settlements.—Asst. Principal of Medical School. $600 per month.

Stannington (Northumberland) Children's Sanatorium.—Female Res. M.O. £250.

Stoke-on-Trent and Stoke Rural Joint Hospital Board.—Res. M.O. £500.

Swansea General and Eye Hospital.—H.S. £200.

University of London.—External Examiners.

West Bromwich and District Hospital.—Res. Asst. H.S. £200.

West Riding County Council.—Dist. Tuberc. O.'s. £600. Asst. M.O. (Res.). £325. Sch. Oculist. £600. Sch. Med. Inspectors. £500.

THE Secretary of State for the Home Department gives notice of a vacancy for an Ophthalmic Specialist Medical Referee under the Workmen's Compensation Act, 1906, for County Court Circuit No. 4, which comprises the Bacup and Rawtenstall, Blackburn and Darwen, Blackpool and Fleetwood, Clitheroe, Garstang, Haslingden and Accrington, Kirkham, Preston and Chorley, and Lancaster County Courts. Applications for the post should be addressed to the Private Secretary, Home Office, and should reach him not later than Feb. 16th, 1921.

THE Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at Portadown, Strichen, Bridge of Weir, and Kilmacolm.

Births, Marriages, and Deaths.

BIRTHS.

ATTLEE.—On Jan. 24th, at High-street, Eton, the wife of Dr. W. Attlee, of a daughter.

BURNFORD.—On Jan. 18th, at Devonshire-place, W., the wife of Dr. Julius Burnford, of a son.

CRAW.—On Jan. 19th, at Northwich, the wife of J. W. Craw, M.B., Ch.B., of a daughter.

GASKELL.—On Jan. 19th, at Nottingham-place, W., the wife of H. S. Gaskell, M.B., Ch.B., of a son.

WATSON.—On Jan. 18th, at High-street, Sheerness, the wife of Dr. F. H. Watson, of a son.

MARRIAGES.

BAIRD—CLARKE.—*On Jan. 17th, Lieutenant-Colonel R. F. Baird,* I.M.S., to Gladys, youngest daughter of the late Richard Clarke and of Mrs. Clarke, of Bexhill.

MYATT—DOHERTY.—*On the 25th January, at St. James's,* Spanish-place, London, W. J. Myatt, of Barnt Green, Worcestershire, and London, to Dr. Agatha Doherty, of 27, Nottingham-place, London, W. 1, and formerly of Toronto, Canada.

DEATHS.

COONEY.—On Jan. 24th, at The Gables, Kingfield, Woking, John Edwin Cooney, L.R.C.P., L.R.F.P.S., L.S.A., D.P.H. Camb., aged 65.

DIMMOCK.—On Jan. 23rd, Lieutenant-Colonel Henry Peers Dimmock, O.B.E., I.M.S. (ret.).

YELLOWLEES.—On Jan. 19th, at Grangeneuk, Fountainhall-road, Edinburgh, David Yellowlees, M.D., LL.D., in his 85th year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Thursday, Feb. 3rd.

OCCASIONAL LECTURE: at 5 30 P.M.
Professor Frederick Hobday: Some Remarks on the Diseases of Animals Contagious to Man (with epidiascope).

MEETINGS OF SECTIONS.

Tuesday, Feb. 1st.

SECTION OF SURGERY: SUBSECTION OF ORTHOPÆDICS: at 5.30 P.M. (Cases at 5 P.M.)

Cases:
Mr. P. B. Roth: Case of G.S.W. of the Elbow.
Mr. Whitchurch Howell: Case of Dislocation of the Hip and Other Deformities.

Other cases will be shown.

At 6 P.M., Dr. G. Murray Levick will give a demonstration on the Reactions and Electrical Treatment of the Intrinsic Muscles of the Foot.

ELECTRO-THERAPEUTICS.—Members of this Section are cordially invited.

SECTION OF PATHOLOGY: at 8.30 P.M., in the Pathological Laboratory of University College Hospital Medical School.
Dr. Penfield: The Golgi Apparatus in Nerve Cells with Special Reference to the Change in Chromatolysis.
Mr. Barrington: Fungus Parasite in Kidney of Rabbit.
Dr. Walshe: A Case of Encephalitis Lethargica.
Dr. Lewis: Laboratory Demonstrations.
Mr. T. W. P. Lawrence: Pathological Specimen.
Professor Boycott: Hypertrophy of Hæmoglobin.

Wednesday, Feb. 2nd.

SECTION OF SURGERY: at 5.30 P.M. (Cases at 5 P.M.)

Cases and Radiographs:
Mr. Gilbert Chubb: Cases and Radiographs illustrating the Technique Employed, and Results Obtained, in the Repair of Fractured Mandible by means of the Free Autogenous Bone-graft.

Paper:
Mr. G. L. Edington: Meckel's Diverticulum as a cause of Intestinal Obstruction.

Thursday, Feb. 3rd.

SECTION OF OBSTETRICS AND GYNÆCOLOGY: at 8 P.M.

A SPECIAL GENERAL MEETING will be held immediately before the ordinary monthly meeting of the Section to consider, and, if approved, confirm, the following alteration in the laws of the Section—viz., that Paragraph 2, Chapter VI. of the laws be amended to read:—

> That the President shall hold office for one year only, and, except by special resolution of the Section, shall be ineligible for re-election.

Short Communication:
Mr. F. C. Pybus: An Unusual Type of a Tuberculous Peritubal Cyst.

Paper:
Dr. T. Watts Eden and Mr. F. Lionel Provis: X Ray Treatment of Uterine Fibroids and Chronic Metritis, with a Record of 76 Cases.

The following have promised to take part in the discussion:—
Dr. Louisa Martindale, Dr. Finzi, and Dr. Gilbert Scott.

Friday, Feb. 4th.

SECTION OF LARYNGOLOGY: at 4 P.M.

Epidiascope Demonstrations will be given by—
The President (Dr. Jobson Horne) and Dr. Irwin Moore.

Cases will be shown by—
Dr. Norman Patterson (two), Dr. Dan McKenzie, and others.

A Report on Two Fatal Cases of Tonsillectomy will be given by Dr. McLeod.

SECTION OF ANÆSTHETICS: at 8.30 P.M.

Paper:
Dr. Rowbotham and Dr. Ivan Magill: Anæsthesia in the Plastic Surgery of the Face and Jaws.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.

MONDAY, Jan. 31st.—5 P.M., Hunterian Lecture:—Prof. W. S. Handley: The Pathology and Surgery of Lupus.

WEDNESDAY.—5 P.M., Hunterian Lecture:—Prof. W. G. Howarth: Mucocele and Pyocele of the Nasal Accessory Sinuses.

FRIDAY.—5 P.M., Hunterian Lecture:—Prof. C. W. G. Bryan: Injuries of the Diaphragm, with Special Reference to Wounds jointly involving Thoracic and Abdominal Viscera.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Jan. 31st.—12.15 P.M., Dr. Burnford: Pathological Demonstration. 2 P.M., Dr. Simson: Diseases of Women. Dr. Morton: X Ray Department. 5 P.M., Lecture:—Dr. A. Saunders: The Digestive Disturbances of Adults.

TUESDAY.—12 noon, Mr. T. Gray: Demonstration of Fractures. 2 P.M., Dr. Pernet: Skin Department. 2.30 P.M., Mr. Addison: Visit to Medical Wards. 5 P.M., Lecture:—Dr. Burnford: Morbid Anatomy of the Digestive Tract.

WEDNESDAY.—11 A.M., Mr. MacDonald: Demonstration of Cystoscopy. 2 P.M., Mr. Addison: Operations. Mr. Gibb: Eye Department. 5 P.M., Lecture:—Mr. D. Armour: Physical Signs and Diagnosis of Abdominal Tumours.

THURSDAY.—2 P.M., Mr. Baldwin: Orthopædic Department. Mr. B. Harman: Eye Department. Dr. Grainger Stewart: Medical Out-patients. 5 P.M., Special Lecture:—Dr. T. S. P. Strangeways: Rheumatoid Arthritis (open to all medical practitioners).

FRIDAY.—9.30 A.M., Dr. Grainger Stewart: Neurological Demonstration. 10 A.M., Dr. McDougal: Electrical Department. 2 P.M., Mr. Banks Davis: Disorders of the Throat, Nose, and Ear. 5 P.M., Lecture:—Mr. Baldwin: Appendicitis. (II.)

SATURDAY.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 12 noon, Mr. Sinclair: Surgical Diseases of the Abdomen. 2 P.M., Dr. Owen: Medical Out-patients.

Daily:—10 A.M. Ward Visits. 2 P.M., In-patient, Out-patient Clinics and Operations.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Jan. 31st.—10 A.M., Mr. W. E. Tanner: Surgical Out-patients. 2 P.M., Dr. A. J. Whiting: Medical Wards. 2.30 P.M., Mr. E. Gillespie: Surgical Operations. Mr. J. B. Bannister: Gynæcological Out-patients. Dr. J. B. Alexander: Medical Out-patients. 4.30 P.M., Clinical Demonstration:—Mr. W. E. Tanner: Selected Surgical Cases. 6 P.M., Dr. F. L. Provis and Mr. T. H. C. Benians: Venereal Department.

TUESDAY.—9.45 A.M., Lieut.-Col. R. H. Elliot and Mr. N. Fleming: Eye Operations. 2.30 P.M., Mr. H. W. Carson: Surgical Operations. Mr. C. H. Hayton: Diseases of the Throat, Nose, and Ear. Dr. Metcalfe: X Ray Department. 3 P.M., Clinical Demonstration:—Mr. C. H. Hayton: Cases of Vincent's Angina. 5.30 P.M., Dr. C. E. Sundell: Children In-patients.

WEDNESDAY.—2 P.M., Mr. C. H. Hayton: Throat Operations. 2.30 P.M., Dr. W. J. Oliver: Skin Department. Dr. J. B. Alexander: Medical Out-patients. Clinical Demonstration:—4.30 P.M., Dr. J. B. Alexander: Cases Illustrating Thyroid Insufficiency. 5 P.M., Dr. Provis and Mr. Benians: Venereal Department.

THURSDAY.—2.30 P.M., Mr. N. Fleming: Eye Out-patients. Dr. A. J. Whiting: Medical Out-patients. Mr. H. W. Carson: Surgical Out-patients. Mr. J. B. Bannister: Gynæcological Operations. Dr. J. Metcalfe: X Ray Department. 3 P.M., Clinical Demonstration:—Mr. H. W. Carson: Selected Surgical Cases.

FRIDAY.—2 P.M., Mr. Howell Evans: Surgical Operations. 2.30 P.M., Dr. C. E. Sundell: Children Out-patients. Mr. E. Gillespie: Surgical Out-patients. 3 P.M., Clinical Demonstration:—Mr. E. Gillespie: Cases of Surgical Interest. 5 P.M., Dr. Provis and Mr. Benians: Venereal Department.

SATURDAY.—3 P.M., Mr. H. W. Carson: Surgical Wards.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Feb. 3rd.—4 P.M., Lecture:—Dr. W. J. Pearson: The Premature Child.

MIDDLESEX HOSPITAL MEDICAL SCHOOL (UNIVERSITY OF LONDON).

TUESDAY, Feb. 1st.—3 P.M., Emeritus Lecture:—Surg.-Rear-Admiral Bassett-Smith: Mediterranean Fever.

THURSDAY.—3 P.M., Emeritus Lecture:—Surg.-Rear-Admiral Bassett-Smith: Malaria.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westmoreland-street, W.

MONDAY, Jan. 31st.—5.30 P.M., Post-Graduate Lecture:—Dr. S. Goodall: Cardio-analysis.

ST. MARYLEBONE GENERAL DISPENSARY, 77, Welbeck-street, Cavendish-square, W.

Post-Graduate Course on Infant and Child Welfare.

TUESDAY, Feb. 1st.—10.30 A.M., Dr. E. Pritchard: Practical Demonstrations on the Management and Feeding of Infants and Young Children—Demonstration V., The Artificial Feeding of Infants.

THURSDAY.—3 P.M., Demonstration VI., The Modification of Milk.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, 49, Leicester-square, W.C.

THURSDAY, Feb. 3rd.—6 P.M., Chesterfield Lecture:—Dr. W. Griffith: Parasitic Diseases of the Skin.

ROYAL INSTITUTION OF GREAT BRITAIN, Albemarle-street, Piccadilly, W.

FRIDAY, Feb. 4th.—9 P.M., Lecture:—Prof. A. D. Waller: The Electrical Expression of Human Emotion.

ROYAL SANITARY INSTITUTE, 90, Buckingham Palace-road, S.W.

MONDAY, Jan. 31st.—5.30 P.M., Prof. H. R. Kenwood: Introductory Lecture to Students attending the Several Courses of Instruction at this Institute.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

TUESDAY, Feb. 1st.—4.30 P.M., Lecture:—Mr. C. Roberts: Treatment of Hernias.

SALFORD ROYAL HOSPITAL AND ANCOATS HOSPITAL POST-GRADUATE DEMONSTRATIONS, at the two Hospitals alternately.

THURSDAY, Feb. 3rd.—4.30 P.M., Mr. Jefferson: Gall-stones. (At Salford Royal Hospital.)

ST. MARY'S HOSPITALS, MANCHESTER, POST-GRADUATE LECTURE, at Whitworth-street West Branch.

FRIDAY, Feb. 4th.—4.30 P.M., Dr. Fothergill: The Interpretation of Physical Signs in Abdominopelvic Surgery.

MANCHESTER BABIES' HOSPITAL.

Post-Graduate Lectures and Demonstrations in the Onward Buildings, Deansgate, or at the Hospital, Slade-lane.

SATURDAY, Feb. 5th.—3.30 P.M., Dr. Chisholm: The Treatment of the Premature Child. (At Onward Buildings.)

Notes, Short Comments, and Answers to Correspondents.

THE DISPENSARY, THE SANATORIUM, AND THE TUBERCULOSIS OFFICER.

THE WEAK LINKS IN A CHAIN.

BY P. C. VARRIER-JONES, M.A., M.R.C.S., L.R.C.P. LOND.,
AND
SIR G. SIMS WOODHEAD, K.B.E., M.D., LL.D.

IN our notes on experiences of colony treatment and "after-care" of tuberculous patients we have, through the courtesy of the Editor of THE LANCET, been able to bring to the notice of our fellow workers our views concerning the solution of the tuberculosis problem as it now presents itself. After close and prolonged study of the position, with due attention to the experience of our predecessors, we definitely conclude that it is impossible to keep different types of tuberculosis in different institutions, and that in the attempt to do so a fundamental error has been committed. In the medical text-book there usually occurs some bald and emphatic statement to the effect that "sanatoriums are institutions for the treatment of early cases of consumption"; upon this basis is founded the whole "sanatorium benefit" of the National Insurance Act; but we are glad to see it is no longer the text and argument on which the most recent report of the principal medical officer of the Ministry of Health is based.

Sanatoriums Intended for Early Cases.

The patient with arrested tuberculosis is able to work at a suitable occupation, and is better mentally, morally, and physically for so doing, but to prevent recurrence of his disease strict limits must be set upon both his work and his play. It is difficult to believe that the contention now generally accepted should have as its basis mere suggestion or hypothesis; but can we find any evidence that it has or ever had any sure basis of observation, experience, or statistics? The understanding that sanatoriums are for the reception of early cases has been firmly impressed on the lay public, and even now it receives lip service, not only from most medical officers of health with whom we have come in contact, but from many tuberculosis officers and superintendents of sanatoriums. But in conversation these men—those abroad as well as those at home—generally make some such further statement as "sanatoriums are *meant* for early cases, but we do not get them; we must therefore do the best we can with the patients that come to hand. We are playing a losing game, but after all, our work is to look after the institution." In other words, it is sought to bend the patient to the system, and not to devise a system that will benefit the patient.

Sanatoriums as Hospitals.

At the dispensaries some attempt may be made to sort out so-called early cases, but very few come under the observation of the tuberculosis officer, and so many middle cases are in such urgent need of treatment that sanatoriums receive very few early cases. The various "public" and "municipal" sanatoriums are practically monopolised by middle and advanced cases, many of which latter are only sent to hospital or home to die. The misreading of the very unsatisfactory statistics published is due to the presence of these cases in sanatoriums; which fact also affords some explanation of the little provision made for the reception and treatment of these more advanced cases. In sanatoriums where high fees are paid some attempt has been made to return to hospital those who are not in an early stage of the disease, but even here the desire to help those in a more advanced stage usually overcomes the discretion of the medical officer. Conditions under which early cases were to be treated have gradually been adapted to treatment of more advanced cases, and the sanatorium has become a hospital for incurables. Indeed, one medical officer of a sanatorium recently declared that he had to run it as a hospital. This state of affairs probably holds in "public" and "municipal" sanatoriums rather than in private institutions, where numerous patients can afford to live for years, and if a breakdown occurs sometimes to return for a further stay. The working man, however, is sent to a sanatorium only when he can work no longer, and then for a period of from three to six months, during which time he undoubtedly improves; only too frequently to break down again later.

False Value of Statistics.

The statement is often made that unless the sanatorium be filled with early cases statistics must suffer. But statistics are already practically valueless with reference to early cases. The patients must not suffer because of the desire of some enthusiasts to obtain apparently good results. Dispensaries and after-care committees should at present take charge of really early cases, but a short term in a sanatorium is an admirable provision to ensure the rest and sanitary or hygienic education which many of them most require. They are neither open cases nor infective, nor a danger to the community; with a short term of sanatorium treatment, with improved home surroundings, regulated work, play, and rest, many of them will do well. Some are sure to require colony treatment at a later period; they must therefore remain in touch with the dispensary, which is the best clearing-house. Dr. James Niven, medical officer of health for Manchester, has thrown the whole matter into a true perspective:—

> "Much dissatisfaction is expressed with the results arrived at from sanatorium treatment, having regard to the heavy expenditure which such treatment entails. This poverty of results was anticipated in Manchester when the sanatorium movement threatened to overshadow the public health preventive aspects of the question, though it was clearly realised by those who had done practical administrative work that the success of other public health measures was dependent on the provision of a certain amount of sanatorium treatment. From the public health point of view—and the successful tuberculosis officer must be essentially a preventive man, even if he is very skilful clinically—what want of success attends sanatorium treatment is largely due to the tendency to regard sanatorium treatment as merely a field for clinical and administrative skill."

Sanatoriums are designed for the reception of early cases only, but they are seldom or never put to their proper use. We must recognise that a comparatively small number of early cases find their way into the beds provided for them; at the same time no adequate provision is made for the treatment of the more advanced cases, probably simply because we ignore the fact that although by far the greater proportion of cases of pulmonary tuberculosis are not early cases they still need special care and treatment. In this connexion a series of definite problems come up for solution.

First, we must realise that all effort will prove fruitless unless treatment and prevention advance together. This brings us to the root of the question. It is sometimes stated that the general practitioner could diagnose all early cases and bring them at once to the notice of the tuberculosis officer, and that this is the only remedy for the present unsatisfactory state of affairs; we have already pointed out[1] that the fault does not lie with the general practitioner; it is the outcome of a desire to accumulate statistics of early cases only, and of our failure to deal satisfactorily with all cases as they come before us.

Professor E. W. Hope indicates this weak spot when he asks:—

> "What, for example, could be said in support of a municipal hospital intended for typhoid fever or small-pox which refused to accept any but those cases which were slight, and were unlikely to add to the mortality statistics of the hospital? After all the sanatorium must be regarded as a link in the chain of sanitation. Its usefulness must not be cramped by exclusion of the very patients who most needed care and attention. In the term "sanatorium benefit," as employed in the Insurance Acts, there were included dispensary treatment and domiciliary treatment, and grants of extra nourishment. All of those measures, however, failed in much the same way that they would fail if applied to any other form of communicable disease which fell short of dealing effectively with the centre of infection."

There now remains no excuse for ignoring the really important middle cases for whose care and treatment so little proper provision has as yet been made.

Professor Hope continues:—

> "It may be asserted with absolute confidence that institutions for the reception of tuberculous patients at all stages of illness are essential for the prevention of tuberculosis, just as in the past hospitals for typhus were essential for the extinction of that disease ...... the exclusive selection of cases with a view to good sanatorium statistics and the limitation of institutional care to those is, from the preventive point of view, preposterous. The point would be made clear by a comparison with the segregation of ordinary infectious sickness."

Mr. White, a member of the Liverpool Public Health Committee, following Professor Hope, and protesting against further classification and segregation, pointed out—

> "that some time ago Dr. Hope appropriated a particular hospital for advanced tubercular cases, and within six weeks the poor people of the city declined to have anything to do with it. Segregation in one ward in the institution was then tried, but the sequel was the same."

Lack of Medical Training in Treatment of Tuberculosis.

One patent reason for this want of understanding and lack of action—we speak plainly on this essential point—is that tuberculosis officers are compelled to treat what they cannot find, sometimes because they are incapable of finding it and sometimes because it is no longer there to be found. During their medical course they have neither been taught to seek nor recognise the really early signs and symptoms of consumption, nor have they had their attention called to the proper treatment of the "middle" cases which in our large towns and cities swarm to tuberculosis dispensaries. There examination of each patient is made perhaps once a week, but the numbers prevent the possibility of more than cursory examination and palliative treatment. Under these conditions little can be done to cure a case or to isolate it and so prevent the spread of the disease. A newly appointed clinical officer, unable perhaps because of his youth to gain the confidence of the general practitioner, finds himself in an ill-defined and insecure position, faced with an extremely complex problem, compelled to work in a groove, with little experience or knowledge of prevention, or if possessing such knowledge, not allowed to use it. He often recognises that the routine work of the dispensary is bearing little or no fruit, but he is kept in a subordinate position and loses heart; his initiative is crabbed and his usefulness crippled. And so often lately has the same story been repeated to us that we do not hesitate to bring the matter under the notice of those interested.

---

[1] Industrial Colonies and Village Settlements for the Consumptive, p. 85.

Not only are costly sanatoriums provided for the reception of cases which do not exist, but a system of dispensary *organisation has sprung up alien to the problem and* therefore inadequate for its solution.

We recognise, of course, that we are again putting forward an unacceptable thesis, as when we formulated the idea of the industrial colony—as opposed to the farm colony—and its natural corollary, the village settlement. Our views upon that subject, however, have now been accepted by many as containing some germ of truth and by a few as sound and completely vindicated, whilst by those who have taken the trouble to study them they have been fairly widely adopted. Dr. W. E. Stewart, the head of the Mountain Sanatorium, Hamilton, Ontario, Canada, has written that whilst good food and fresh air are no doubt essential agents in the treatment of tuberculosis, so also are regulation of exercise and rest, freedom from anxiety, mental occupation, and content.

> "Each case presents new features for consideration, and only the *skilled and trained man is capable of applying* the new general principles on which treatment may be successful. ...... An outdoor occupation may be preferable to an indoor one, other things being equal, but the trouble is that other things cannot and never will be made equal. If weather were always good and jobs as varied, suitable, light, and remunerative outside jobs would be chosen, but suitable indoor jobs are much more numerous."

Work for Consumptives.

The tuberculous man must learn to live the life of a consumptive, and he must be provided with permanent work. Blind-alley occupations are not for him; he must be capable of earning as much as possible to the end, for at the end he will require it most. Dr. Stewart puts the matter both tersely and forcibly thus:—

> "A workman's trade is his capital, slowly acquired like a merchant's business, and to ask him to give it up is like asking the merchant to burn down his warehouse, destroy all his records, cancel all his contracts and commissions, and begin, without resources, to build up another and a different business." Further, "when a workman trained in a trade gives up that trade and begins to learn a different one the loss to the individual and the State is the same kind of loss as the burning of a factory. It is a destruction of an asset, personal and national. Teach a clerk to become a secretary, a machinist to develop into a draughtsman, make a carpenter a supervisor of work, and you are on the right lines."

The sanatorium idea was an application to the working man of the treatment of the well-to-do, without any careful study of the principles involved; similarly, the format of the dispensary was that of the physician's consulting-room. In the one case the patient can afford to take the proffered advice, but in the other no advice or persuasion will induce the working man, if he is an early case, to accept the label "consumptive," to be harassed by health visitors and sanitary inspectors, and to give up a remunerative occupation for the "open-air job" offered in exchange. At this stage, when the man is not yet dangerous to the community, *sound advice* as to home conditions and social life coupled with a term of rational sanatorium treatment (if he can be persuaded to accept it, and if the sanatorium is not filled with middle and advanced cases) is the most satisfactory line of procedure. So long as we adhere to the accepted inexact classification and irregular system of case grouping we can expect no larger return in the matter of prevention. We know that had we no centres of infection we should have no early cases of consumption to deal with, but our efforts to remove these centres are half-hearted. It would be impossible at once to remove all centres of infection, but we should not on that account relax our endeavours. Every tuberculosis officer and every medical superintendent of a sanatorium, now often engaged on mere routine work, should be asked to concern himself with some really constructive policy into which he can throw both mind and heart.

Difficulties of the Tuberculosis Service.

The young tuberculosis officer takes his place under an able administrative chief, in whose person are combined the function of medical officer of health, school medical officer, and chief tuberculosis officer, but who, in the very nature of things, can have little special knowledge of tuberculosis. We are told that tuberculosis touches many sides of administration, housing, sanitary questions, and the like; that these *are essentially the concern of the medical officer of health*, and that no alteration or variation of the scope of the latter's powers can be made with impunity. We admit that the problem is full of complexities. Medicine, sociology, economics, psychology are woven into the web of the tuberculosis question as they are into that of no other disease afflicting civilised man. As Sir Arthur Newsholme has written: "The greater part of a consumptive's life is spent at home, often under unsatisfactory conditions both for the patient and for his family, and the supervision of his home life by the tuberculosis officer and the health visitor, even when this is frequent and sympathetic, does not meet his needs. If the patient is to have the best possible prospect of recovering, and if his family are to be safeguarded against infection, he will in many cases need (*a*) improved housing, (*b*) occupation adapted to his physical capacity, &c., &c., (*c*) the family income will need to be supplemented. These requirements have not hitherto been met."

We would ask what chance is there of these conditions being met under our present dispensary system? The dispensary medical officer—probably well trained in ordinary clinical diagnosis and treatment, but with little knowledge of consumption and the consumptive, bound by the rules of an inelastic service, subservient to a chief whose duties prevent any practical contact with him—is discouraged and hampered on all hands. We say the system is wrong, and except in rare and notable instances a complete failure.

Dr. F. J. H. Coutts, commenting on Dr. J. E. Chapman's report,[2] corroborates Dr. Niven's contention that the tuberculosis officer too frequently approaches the tuberculosis problem from a purely clinical point of view, ignoring the wider outlook of preventive medicine; and so long as he is regarded as being in charge of a tuberculosis dispensary or of a sanatorium; so long as his duties consist merely in making so many visits, attending so many hours, and providing such-and-such statistics; so long as he is not expected to show any initiative or devise plans and methods of general treatment; so long must he be simply an appanage to the public health department. Moreover, it must be recognised that some tuberculosis officers never had any opportunity of acquiring either the necessary administrative experience or the requisite special knowledge or technical skill before they were called upon to take up their special work.

Tuberculous patients cannot be classified and labelled "Stage 1," "Stage 2," or "Stage 3," and so left. Little progress can be made until the system, or lack of system, now in vogue is altered, and the hand of officialdom is removed. The motive power at present must be applied from below by personal endeavour and original research, for in many areas rules and regulations are alone considered necessary. We are glad to see that in the most recent report of the principal medical officer of the Ministry of Health this outlook is disavowed and discouraged.

Improvements Necessary for Advancement.

Writing from time to time on the colony system for the treatment and prevention of pulmonary tuberculosis, we have always insisted that it can be but part of a larger whole. Speaking generally, we have been astounded to find how stereotyped and even discredited methods have been allowed to assume sway even in a new medical service. Sir Henry Gauvain's message quoted in the *Times* report of the Liverpool Conference of the National Association for the Prevention of Tuberculosis should give us pause: "Our army is ill-trained, ill-equipped, ill-organised, lacking in leaders with full powers to act." The head of the tuberculosis department should not be hampered by too varied duties or enmeshed in red tape; he should possess more than knowledge which at the worst is *incomplete and at the best can* be obtained only secondhand; and he should have ample time and facilities to study experiments, observations, or publications bearing on his own work. He should also be able to advise, direct, and superintend a really virile attack against the disease. Nothing effective can be done when, as in many instances, the elements of knowledge and experience are lacking. The tuberculosis officer cannot perform his duties even passably well unless he possesses a real working knowledge of (1) the extent to which treatment of patients in their own homes is beneficial; (2) how far work (which is a therapeutic measure) can be arranged for, either in a borough or county area; (3) the economics of the problem; (4) the home conditions of the people and the relation of these to questions of infection; (5) workshop and factory conditions; (6) hours of toil and industrial fatigue—in short, a knowledge of the whole complex of conditions involved in the medical, social, and psychological study of the disease.

---

[2] Annual Report of the Chief Medical Officer to the Ministry of Health for 1919–20, p. 149.

Few tuberculosis officers have been encouraged to apply themselves to these various studies, and few are able to supply information, even on the most important matters concerning their patients. These are faults of the system under which they work, coupled with the lack (except in one or two specially favoured schools) of training of medical men in the diagnosis and treatment of tuberculosis. The tuberculosis officer struggles on with mere routine examination of chests, seeking early cases, missing some, labelling others; the latter, whatever their stage, are passed through the same routine treatment of a few months' residence at a so-called sanatorium, which is very often an annexe of an infectious diseases hospital or some similar makeshift. His work is judged almost entirely by the number of examinations he makes, for the figures he provides help to make impressive the annual report.

Weaknesses of the Dispensary System.

Work is being done, but that this work is productive of little good seems beside the question. The Ministry of Health has laid it down that patients must be seen and treated at a dispensary. The tuberculosis officer must continue to examine and report. How greatly would it benefit the patient and the community if the tuberculosis officer were encouraged to deal with a case thoroughly, and to offer the consumptive an opportunity to lead a reasonable life, doing his 30 per cent. or 50 per cent. of work under conditions in which the danger of infection to others had been eliminated or reduced to a minimum.

The expert knowledge which the tuberculosis physician should possess might then be utilised to its fullest extent; constructive work would occupy his thoughts and energies. The value and results of medical examination of patients and contacts would be increased a hundredfold. The full return for medical advice would be obtained, for the patient would have the opportunity to benefit by it. What action is possible in the case when patients are passed through the dispensary at the speeds of which we constantly hear? Can we wonder that the dispensary system runs a danger of being set down as a gigantic failure?

A mere examination, a mere visit of the tuberculosis officer to a patient's home, can neither ensure treatment nor prevent the spread of disease. Not only in counties but in county boroughs the death-rate from tuberculosis and the number of notifications have failed of late to decrease as they should despite the recent advances of medical science; yet the old routine is adopted or still followed. The tuberculosis dispensary is apt to become a field for little more that a poor-class panel practice devoted entirely to tuberculosis—an out-patient department, stocked with drugs which are mostly placebos, or an annexe of an office for the compilation of statistics. Such was not, as we read it, Sir Robert Philip's idea and plan of the dispensary system, which appears to have degenerated into its present hidebound condition, with a personnel isolated and of no importance in a scheme in which it should form a central pivot. The dispensary officer, the sanatorium physician, and in some localities the colony superintendent, are kept in their little compartments; there is no expert head, for the medical officer of health of any large area has obviously neither the time nor the special training to enable him to assume the control of a complete tuberculosis scheme.

Conclusion.

When we see the immediate and satisfactory results obtained in the industrial colony and by the after-care system, and have practical demonstration of their smooth working and adaptability to the existing problem: when we recognise the widespread desire to copy the system and put it into practice in areas other than Cambridge, we are compelled to conclude that there is still much to be done before the treatment of the tuberculous patient is satisfactory. It was anticipated that sanatorium benefit was about to be handed over by the Insurance Committee to the public health authorities, and that a thorough transformation might be possible; but the opportunity has been allowed to go by, for the present at any rate, but let us hope that we may not be compelled to pass through a further period of inaction and of abject failure to stem the progress of tuberculosis.

LIFT ACCIDENTS IN PARIS.

THE large and increasing number of accidents in Paris lifts was the subject of a report recently by M. Walckenaer, the Inspector-General of Mines.[1] The report covers the period 1905-1919 in which there occurred no less than 94 accidents, of which 37 were fatal. The numbers of accidents in 5-year periods were 22, 32, and 40. More than half the accidents were due to crushing between the framework of the lift and one of the floors or ceilings of the building. It is recommended that automatic stoppage should be enforced, so that whenever the lift door is open no movement is possible. This device would have prevented the greater number of the accidents, but in order to enforce its adoption it will be necessary to exclude all lifts not worked by electricity.

EARLY CARCINOMA OF THE BREAST: A QUERY.

F.R.C.S. writes: In works on surgery written about 1850 and also since, references are given to a case of very early carcinoma of the breast in a child, and in every case the reference is the same: "Lyford, LANCET, vol. xii., p. 332." Unfortunately, no account of this can be found in the place indicated. Also another reference is made to a case of early carcinoma reported by "R. Carmichael": in this case no book is mentioned. I shall be greatly obliged if any of your readers can give me the correct references to these two cases.

A. A. D.—We have not before us the circumstance which has led to the indignant communication. The Registrar keeps the official Register of qualified medical practitioners. The purpose of the Register is to enable the public to discriminate between those who are and those who are not qualified. If the Registrar is not informed of the address of a member of the medical profession, after due preliminaries the name must be removed. For, obviously, if the Council are not aware of the continued existence of the practitioner, to allow his name to remain on the official list is to invite impersonation, by which the public would be swindled.

Communications, Letters, &c., to the Editor have been received from—

A.—Dr. D. K. Adams, Glasgow; Assistant Registrar-General, Lond.; Dr. A. Abrahams, Lond.

MEDICAL ... LIBRARY

Two Addresses

FUTURE OF THE POOR-LAW INFIRMARIES.

Delivered at the Resumed Discussion before the Harveian Society of London on Jan. 27th, 1921.

I.

By A. G. STEWART, M.A., M.D. F.R.C.S. EDIN.,
MEDICAL SUPERINTENDENT, PADDINGTON INFIRMARY.

IN considering the future of the Poor-law infirmaries it is essential to understand the present position of affairs, and I beg to thank you for allowing me to try to explain some matters which, judging from some of the remarks of previous speakers, are not understood. Too frequently criticism consists of vague general abuse. Definite charges can be met, and they at any rate serve a useful purpose, inasmuch as they form a basis on which to discuss improvements. The problem of the Poor-law infirmary as regards London and the larger towns is somewhat different from that in country districts. In the former the infirmaries are under separate administration, and are naturally better equipped than in the latter, where there are special wards in the workhouse for the sick. I think it fair to make this point, just as previous speakers in referring to voluntary hospitals were obviously thinking of large teaching general hospitals and not of cottage hospitals.

THE MYTH OF THE CHRONIC AGED PAUPER.

About 40 years ago the general voluntary hospitals treated all acute cases. The function of the infirmary was to provide for the chronic and incurable sick, and they were staffed and equipped on this assumption. During the past 30 years there have been great strides in medical treatment and naturally a much bigger run on the beds of the hospitals. It is now admitted that the voluntary hospitals can no longer cope with all the acute work of the country. At any rate, those cognisant of the position know that for many years the infirmaries have had to treat many cases of fracture and other accidents, and of broncho-pneumonia, as well as miscarriages, and such emergency surgical work as "acute abdomens." The medical profession generally would be surprised if it knew the extent of this work. May I be allowed to give a few figures to contradict a prevalent idea that infirmaries only treat chronic cases? I am purposely quoting pre-war figures so that it may not be thought that the war has produced these changes. For the year 1914 50 per cent. of our total cases admitted made a stay of less than one month, and 75 per cent. less than two months. As the average duration of stay in such hospitals as University College, Westminster, &c., is 37 days (for all figures referring to voluntary hospitals I might say my authority is the last edition of "Burdett's Hospitals and Charities"), it will be obvious that some 60 per cent. at least of our beds catered for the same class of case as the voluntary hospitals. I only refer here to the question of duration of stay. Applying this to Mr. E. W. Morris's own figures for the whole of London we find 12,000 infirmary beds dealing with acute cases, whereas the total hospital beds in London number 14,000. Yet it is actually stated that we treat "only chronic and incurable cases." This is the kind of criticism to which I maintain we have a right to object. Again, to contradict a common opinion that we deal only with the aged, I might add that 18 per cent. of our admissions were under 8 years of age, 30 per cent. under 10 years, and only 20 per cent. over 60.

Another prevalent opinion is that the infirmaries deal with the sick of the workhouses, or, in other words, with paupers. It is constantly being said that they are so unpopular that people are unwilling to enter them. Even such a great authority on hospital matters as Mr. Morris, of the London Hospital, stated at the last meeting that the Poor-law infirmaries should not be confined to paupers. I was told only the other day by the medical superintendent of a large South London infirmary that for the past year only 8 per cent. of his cases came from the workhouse; and in the year 1914 only about 20 per cent. of our admissions were workhouse patients. The great majority of our patients are hardworking people whose only need of relief is due to their sickness. The infirmaries were originally provided for the "destitute," but it is not perhaps generally known that the Local Government Board's definition of destitution has for many years been very elastic, and really means inability to provide for oneself the particular form of medical attendance or treatment of which there is urgent need. The other day I asked the clerk to the guardians if he would kindly work out the numbers of patients in the infirmary who paid towards their maintenance, and I was surprised to find that over 60 per cent. did so.

OUR EQUIPMENT.

We are told that there is a prejudice against Poor-law infirmaries. This is a trite saying. Old members of our lay staff apply for treatment, and I have been told by several general practitioners in this district that their patients prefer the infirmary to the hospital. I venture to prophesy that some of the squeamish objectors will find their prejudices diminish when the voluntary hospitals begin to charge, as we have done. It would be better if instead of talking of stigma someone would give a little attention to the mediæval and complicated law of settlement, which is responsible for much of the prejudice against the Poor-law. It is this antiquated law which is responsible for the apparent reluctance to make the infirmaries as accessible as they might be to anyone seeking admission there. Some boards of guardians have actually anticipated Parliament in trying (partially, at any rate) to adopt commonsense measures to unravel this bundle of red tape. The character of the work has thus immensely changed. While I freely admit that we were not equipped or staffed to meet this demand as we should have liked, I resent the remarks that we provided little more than food and shelter.

When war broke out many infirmaries all over the country were taken over as military hospitals—not as auxiliary, but as first-class hospitals. The staff and equipment were taken over, and according to the Army Council carried out the work satisfactorily. For years we have been doing such work as bone-plating and grafting, using spinal anæsthesia and local anæsthesia for serious operations, and doing hundreds of acute abdominal operations yearly. The Harveian Society has seen such cases as successful resections of carcinoma of the bladder and stomach, and of brain abscess and gangrenous intussusception done at a Poor-law infirmary, which in some ways is much inferior to many others. The statement that there was no provision of X rays or pathological facilities is quite incorrect.

OUR NURSES.

As regards our nursing, I maintain that our nurses in the separate infirmaries are as well trained, at any rate as regards private nursing, as the general hospital nurse. The more up-to-date infirmaries have appointed special sister tutors; have all hospitals done so? Training is given in special subjects, and several of us prescribe a four years' course of training, whereas the usual hospital period is three years. Examinations are held by outside examiners, of whom I see some here to-night. I have recently got some of our consulting staff to give lectures in their special subjects. Again, owing to the much greater variety of cases seen and the absence of students, the infirmary nurse has had certain advantages, and the very fact of our limitations has made the work more akin to what she has afterwards to do in private nursing.

The numbers of nurses in proportion to patients have greatly improved in recent years and are still improving. In this connexion one might fairly ask why there is such a tremendous disproportion between even the great teaching hospitals as regards numbers of nurses, and to suggest that if there were anything like agreement we would then have a standard to which we might refer. In admitting that our equipment and staffing were not all we should have liked I do not think it fair to blame the guardians altogether, as is usually done. If there was in some quarters the tendency to adopt the attitude suggested by Mr. Morris—"Why should we provide costly equipment when we can get the work done for nothing?"—it should be ascribed to public opinion, which was not alive to the actual situation, or, in other words, would not sanction the necessary money, and we cannot expect an A1 hospital on C3 expenditure. The change of feeling in such matters caused by the war, and the appreciation of the inadequacy of accommodation for the sick, has stirred public opinion, and the guardians have responded to this feeling, as they would have done years ago had the feeling existed. Many of these boards take a surprisingly broad point of view, devote a great deal more time to their duties and have a much more intimate knowledge of the work than have the directors of general hospitals. You would be surprised if you knew the amount of work supposed to be carried out by other authorities which in practice is referred to and done by the guardians, who merit the credit for the same. At any rate, whatever our view as doctors may be as to the governors of hospitals, we must awake from dreams and remember that we are living in the democratic twentieth century and not in the feudal age. We ought to be represented on the governing bodies of hospitals, but to expect a 50 per cent. representation, as Mr. Morris suggested, is only to invite disappointment.

I feel bound to say that in the past we had very little help from the profession generally in backing up our requests for improvements, although I feel it only fair to mention the exception of the Harveian Society for what I believe to have been its pioneer action in pre-war years of holding some of its clinical meetings at our infirmary, and thereby giving us a little encouragement.

Another complaint is the lack of classification. This has always been a difficulty. We are not like the voluntary hospitals which set aside wards for certain classes of cases and largely fill up their vacancies from waiting lists, nor like the fever hospitals or asylums which refuse more cases when their beds are full. We are the only institutions whose beds are supposed to be inexhaustible, and who are compelled to take in all medically deserving cases, however full we may be. We treat most infectious diseases, apart from scarlet fever and diphtheria, and in short, all the numerous cases which the hospitals send to us, often for the very reason that they are difficult to classify. It was one of the great merits of Dr. Addison's Bill that classification would be greatly improved.

THE FUTURE OUTLOOK.

May I now turn to the future? I think that the problems are too often approached from the purely medical point of view, and it is apt to be forgotten that the prime function of the hospital is to treat the sick and to render the patient a useful member of the community. If this were properly appreciated it would be evident that there need be no rivalry between the infirmary and the general hospital. Each of them has a future and I beg to differ from Dr. Wilson and to submit that each has a great future, and that the futures are not the same.

I believe that the voluntary hospitals will have to consider the problems more from the scientific, research, and teaching sides, and to approach them essentially as specialists, whereas we have to tackle mainly the economic aspect of the cases and approach them from the point of view of the general practitioner. If this were done, and especially if there were some central authority to coördinate our efforts, great improvements could be effected and much money saved.

We are accused of lacking the most advanced scientific and research apparatus. I retaliate that this is not essential, especially in these days when economy must be considered, and say that the hospitals, in their excess of scientific zeal, have sometimes not seen the wood for trees. For instance, I know it requires much more skill and brains, and brings more kudos, to treat a case of spina bifida than to treat a broncho-pneumonia, but, assuming that each survives, perhaps the broncho-pneumonia will turn out the more useful member of the community. After all, is it right that cases of acute enteritis and burns should be turned away from hospital when the beds are occupied by cases of infantile diplegia or new growths of the kidney? I say it is *only* right if you provide the former with places to go to, and this is where the infirmary comes in. If our work were coördinated, beds for certain rarer types of disease, such as goitre, cleft palate, and cerebral tumours, could be set aside in hospitals where there were surgeons especially experienced in such work. As a matter of fact this is done in practice to-day, but it should be regularised, so that there can be no question of the general practitioner being unable to get less dramatic but equally deserving cases admitted. Now, if this principle were admitted the work could be better done and economies effected—e.g., in the way of unnecessary reduplication of equipment.

If the infirmary is to do the routine but not less useful work, it follows that the methods of staffing and administration which are best for the hospital are not necessarily the best for the infirmary. I think there is much in the suggestions of Dr. Charles Buttar and Mr. Basil Hall, of Leeds, that the infirmary posts should be paid and allocated to junior men. In the past it has been extremely hard for young men without money to specialise, and in the future the way must be made easier and brilliant men must not be lost for this reason. I think there is no necessity whatsoever for all cases in the future infirmary to be under specialists, as they are in voluntary hospitals. In fact, there might be a danger of the old complaint of admitting from the point of medical interest and not from that of the patient and of the State.

In this discussion every speaker—specialist, layman, and general practitioner, and, I confess, myself—has rather had the tendency to consider the poor chronic incurable as something undesirable. In fact, some speakers actually referred to him as rubbish. I have heard this type of case referred to also as the gold-bearing goose, but perhaps the nomenclature varies in the Harrow-road and Bayswater. I think I can fairly claim that I am not biased against the specialist; at any rate, I have made every endeavour to welcome him to my own infirmary. But I do say that a large part of our work can be done equally well by the general practitioner. I submit that the definition of a general practitioner is not one who puts up his plate and is paid by fees, but one who treats the average ordinary case of sickness. I do not in the least see why we should not have part-time general practitioners on our infirmary staffs, provided, but only provided, they demand sufficient remuneration to justify their giving the necessary time to the work.

The Training of General Practitioners.

Again, we can do a useful work—as, I submit, we have done in the past—in training our residents (for we must have some whole-time residents) to become useful general practitioners. We have had in the past very many capable young residents who have nearly always come to us after holding resident posts at one and sometimes three or four hospitals. Now such a staff of general practitioners, or young men with two or three years' post-graduate experience, naturally expect more responsibility than do the newly qualified house surgeons of a voluntary hospital. The consultant should correspond to the consultant in general practice and assist and advise, but not displace, the general practitioner. One of the duties of the medical superintendent would consist in linking together the staff, in seeing that the requests of the general practitioner for advice were acceded to, and, in short, in promoting the spirit of team-work. Team-work must include the general practitioner, who has too often in the past lost all contact with his patient when he has entered hospital.

In prophesying that the infirmary of the future will be for the ordinary types of disease, I do not mean to suggest that there is no scope for research work or for students.

On the contrary, the infirmaries would serve a useful purpose, for too often in the past it has been forgotten that the average student is going to be a general practitioner and not a specialist, and he will see in the infirmary cases which will be as useful to him afterwards as the rarer cases to which he now devotes such a large part of his energies. But I do repeat that our main function is treatment. In suggesting that there is a future for both the hospital and infirmary it matters not whether the former remains voluntary or comes under the State, provided that the work is coördinated. In this connexion one comes to what is probably the greatest change made by the voluntary hospital in recent years—namely, the proposal to charge those patients who can afford to pay. In passing I might be allowed to call your attention to the fact that this is what we have been doing in the Poor-law institutions for 30 years. I believe the change is fraught with far greater consequences than the hospitals possibly recognise, and I believe that both the Poor-law and the hospitals are entirely wrong in the principle, as this is opposed to the modern tendency of insuring against all evil.

The Time to Pay.

Surely the time to pay is when a man is well, and not when he is ill and out of work. The State has admitted its liability to treat the working man for minor illness under the panel system, and the principle has been accepted by the medical profession. Is it not logical that the State should assume the responsibility of treating the working man when he develops pneumonia or breaks his leg? And can anyone doubt that the working man is going at some time (sooner or later) to demand this, and demand it not as charity but as a right? Is it not fairer that all should have to pay their share by some such scheme as an extension of insurance contributions rather than by optional weekly voluntary contributions, as is done in the north? The great objection raised against the voluntary hospitals coming under the State (in some form) is the fear of control or, in other words, supervision. But is not some form of supervision or some central controlling influence desirable (I refer not to the medical but to the lay aspects of the case)? Let us turn to the question of expenditure.

THE DESIRABILITY OF ADMINISTRATIVE COÖRDINATION OF VOLUNTARY HOSPITALS.

As regards in-patients, after deducting the cost of rent, rates and taxes, and out-patients, the average cost per occupied bed in the hospitals of England varies tremendously, e.g.:—

In 5 hospitals the cost is over £170
" 14 " " from ... ... £140 to £150
" 18 " " " ... ... £120 " £130
" 22 " " under £90

As regards the cost of out-patients (calculated on hundreds of thousands of cases) if one takes four leading London teaching hospitals the cost per out-patient is 3*s.* 2*d.*, 4*s.* 2*d.*, 7*s.* 4*d.*, and 7*s.* 8*d.*

Perhaps these figures can be explained, but am I wrong in suggesting it is desirable there should be some central authority to investigate such matters, and perhaps suggest the probability of certain economies, just as all our expenditure is subject to the scrutiny of the Ministry of Health? Again, the question of the tremendous variation in the duration of stay in different hospitals should be looked into (17 to 38 days in London teaching hospitals). This should be done not merely from the statistical point of view. It might, for example, be found out what is the percentage recurrence after operation for hernia in the hospitals where the average durations of stay are 17 and 38 days.

Again, I do not think that the administration of hospitals is perfect, in spite of their being held up to us as models to copy. Such questions as dietaries, the question of explaining operations to patients' friends, &c., are left to the house surgeon or to the nurses, and frequently are nobody's business. The young house surgeon—and I speak from wide experience—does not, as a rule, appreciate the importance of such matters, however good his scientific training may be. After all the patient's friends will forgive you if you fail to diagnose the exact form of one of the muscular dystrophies when he will not forgive you if you forget to send out till too late a notice that his mother is dying. In support of my suggestion that a more human point of view is desirable, might one ask if any member here can recollect any of our numerous medical societies discussing, or any papers in our leading medical journals dealing with such subjects as the possibility of improving our gloomy out-patients departments, or cutting down the hours of waiting there by some attention to method? Or, again, with the possibility of tracing the medical history of patients who migrate from one hospital to another?

Can it be denied that if one-hundredth part of the brains and trouble which have been applied to the question of, say, gastric analysis had been applied to such problems the results would have been worthy of that attention. It is no answer to say that these are not questions for the medical staff. They are somebody's business; in the past they have too often been nobody's.

CONCLUSION.

In conclusion, I think it right to explain that any remarks I have made should not be construed as reflecting any disappointment with the arrangements made between St. Mary's Hospital and my infirmary. So far as I am concerned, the scheme has worked smoothly and well, and it might be interesting to add that throughout the past year only one patient has complained of the presence of students.

II.

BY R. DUDFIELD, O.B.E., M.A., M.B., D.P.H. CAMB.,
MEDICAL OFFICER OF HEALTH OF PADDINGTON.

"Salus civium civitatis opes" may be bad Latin, but it expresses what is the guiding principle of my official work. I regard the health of the citizen as the greatest asset of the nation's wealth, and I therefore regard it as an economically unsound policy to leave sick citizens to their own devices.

PROTECTION OF THE PUBLIC HEALTH.

I thus believe it to be to the advantage of the community that the State should assume the care of the sick. In these days few would seriously dispute the State's right to take measures to prevent disease, and I think that it is becoming generally recognised that the care of the sick—which phrase I do not limit to the treatment of those who are acutely and dangerously ill—must be regarded as a national duty. There are, of course, sections of the population well able to take care of themselves. With those sections the State does not need to concern itself directly, though even for the sick among them the State should not fail to have some regard. There remains a larger section of the population, composed mainly of the producers of the nation's more material wealth, whose members are just able to maintain themselves when in full health and efficiency, but when overtaken by disability in any form are faced by poverty and, possibly, more or less permanent inefficiency. If the members of this section be adequately helped in the time of stress and their efficiency restored they can resume their places in the social world as producers. If they be neglected, they tend to become a burden and drag upon the community. Self-protection should stimulate the community to look after the sick citizens and to take all reasonable steps to set them upon their feet again at the earliest possible minute.

Since the great stocktaking of national health which was incidental to the medical survey of recruits for the Services, much emphasis has been laid upon the necessity of searching for and treating the beginnings of disease. At present it is but rare for a failing man—who is not necessarily a sick man—to seek medical advice. Apart from the difficulty of finding money for the doctor's fees, the failing man fears an order to slow down in his activities, and he fears still more the financial stress which would inevitably ensue from such slowing down. We cannot expect to obtain sufficient material for the study of the beginnings of disease until the State steps in and relieves the failing man of some, at least, of his burden.

The State as a Charity Organisation Society.

It may be argued that these views would make the bulk of the population paupers. I admit that I personally am unable to appreciate the difference between State (or municipal) assistance and Poor-law relief—a distinction which is strenuously insisted upon by certain schools of thought. To my mind the only difference lies in the taking of money from the right pocket instead of the left. I would, however, ask you to look at the proposals from a different point of view. Why should not the State be regarded as a National Charity Organisation Society? The designation is not, perhaps, altogether a happy one, but it will serve my present purpose, as it connotes principles which I think should govern the relationship of the State to the failing and sick. I do not want to see the State taking over the whole of any man's responsibilities, but I do think it would be to the advantage of the community if the State came forward and gave so much help as would tide the man and his dependents over the hard times so frequently associated with disability of the breadwinner.

Protection of the Public Wealth.

In any such scheme of State assistance medical treatment would take first place. The home conditions of that section of the population whose sick should be the care of the State are rarely such as to afford the best chances of speedy restoration to health and efficiency. Too often the patient is in need of removal to a more favourable environment. Accommodation is provided in isolation hospitals for the dangerous infectious diseases, the object of such provision being not so much the treatment of the sick man but the protection of public health. My proposals imply the removal of the sick man for the *protection of the public wealth*, to secure his early return to full working capacity and, if humanly possible, to prevent him becoming a permanent burden on the State. I am not proposing that every failing or sick man should be provided with accommodation on the standard of our general hospitals. I should be satisfied with something far less costly which can, I think, be provided by the infirmaries—remodelled and improved as may be found necessary. Incidentally, I may observe that I am thinking of infirmaries as I know them, which means of the standard general in the metropolis. I have had opportunities of watching the improvements in standards and work of those infirmaries during the past 30 odd years. The infirmaries, or new hospitals, which is the term I would use for them, having been transferred from the Poor-law to the municipal authorities, should be managed by the ratepayers. I wish emphatically to dissent from the suggestion put forward by Mr. E. W. Morris that ad hoc authorities should be set up. We have had too many creations of such authorities in the past. At the present time London is seeking a way to get rid of some of them. Ad hoc authorities are too frequently wasteful in personnel and administration, and too often beyond the control of the ratepayers, who have simply to foot the bills presented to them and look as cheerful as they can. The existing authorities—county and municipal—are fully competent to undertake the administration of hospitals, and they will, I am convinced, do it more economically than any ad hoc authority. I suggest that the infirmaries be made into municipal hospitals, when they would fall naturally into place as "primary centres," should the scheme for the provision of medical treatment embodied in the "Dawson Report" ever be brought into operation.

The County Council as Authority.

If the infirmaries be taken from the Poor-law, to which authority should they be transferred? In dealing with this question I speak as a London man, preferring to leave extra-metropolitan policy to be thrashed out by those who are better acquainted with the needs and umstances of extra-metropolitan areas. The Maclean rt (1918) recommended that the infirmaries in don should be transferred to the County Council. recommendation was endorsed by the Conference Representatives of Metropolitan, City, and Borough uncils in June last. Although apparently not in harmony with the general tendency towards decentralisation and strictly local self-government, there is a good deal to be said in favour of the recommendation. There is a growing tendency to make the County Council the authority for providing treatment in residential institutions for residents in the county. In the present instance I think that the transference to that Council will lead to economy, firstly, because it is probable that fewer infirmaries will have to be taken over, and, secondly, because probably fewer beds would thus remain empty.

The Medical Staff.—Linking-up.

There can be no doubt as to the necessity of a resident medical staff, the personnel of which will depend on the number of beds and, possibly, the class of cases for which the hospital is reserved, if any classification of hospitals be introduced. I do not consider that the whole of the visiting staff should be consultants. I should like to see the local practitioners acting as visiting physicians and surgeons. Here I join issue with Dr. Charles Buttar, who appears to have doubts as to the possibility of such proposal. Local practitioners are very successful in working hospitals in the smaller provincial towns, and I cannot see why they should not be equally successful in the new hospitals. I should propose that rotas be formed of those practitioners willing and, might I add, fit to work in the hospitals, and that they take limited periods of duty. It might conceivably be possible to allow an individual practitioner not on the staff of the hospital to continue his treatment of his patient after admission, should the doctor and patient so desire. It should not be beyond the wit of man to frame the rules necessary to meet the special case. The experiment of linking the local infirmary to St. Mary's Hospital has been so successful that there can be no doubt that such linking-up will become general in the future. The staffs of the general hospitals so linked to the new hospitals will become the consulting staffs of the new hospitals; the association of students with the new hospitals will then be taken as a matter of course.

Conditions of Admission.—The Voluntary Principle.

I doubt whether the general hospitals will be able to rely upon voluntary contributions much longer, and it is probable that the establishment of the new hospitals may hasten the time when the general hospitals will be obliged to accept municipal or State help. When that time comes the general hospitals will admit ratepayers on the same conditions as the new hospitals, and transfers between the two classes of hospitals will be regarded as quite usual. Until that time I should like to see some system of priority of admission to the general hospitals accorded to special patients in the new hospitals.

Every ratepayer, subject to conditions to be stated later, should have the right of admission to the new hospitals, if such admission be certified as necessary by the practitioner in charge of the case. I do not mean that a ratepayer to whom a certificate may be issued should be able to go to the hospital with the certificate in his hand and demand, and obtain, a bed. The applications and certificates will have to be sent to an official charged with the regulating of admissions. Control will be necessary to prevent irregularities in admission and will be the more necessary if any allocation of hospitals to groups of disabilities be adopted. A central control will be required to prevent any one hospital being overpressed with cases while another hospital stands half full. Whenever a complete scheme of convalescent homes, &c., becomes operative, central control will be required to regulate the flow of patients from one institution to another.

I have said that every ratepaper should have a right to admission to the new hospitals. Such right should not, I think, mean free treatment in every case. Whether or not the new hospitals afford more than one standard of accommodation—the treatment would be the same for all—the principle of assessment, now enforced by the County Council in connexion with the treatment of the uninsured tuberculous, should be adopted with regard to admission to the new hospitals. If all paid in proportion to their means, the cash received plus the amounts paid by the Insurance Committee on behalf of insured persons would materially lighten the burden of the new hospitals on the rates.

While no one would be compelled to enter hospital, I think that entry into hospital should, in cases for which hospital treatment may be certified necessary or desirable by the medical attendant, be made a condition precedent to the granting of financial help to the sick man's dependents. State help for the dependents is, in my opinion, an essential for the success of the scheme I have outlined, but the State is bound to consider economy. It would be wasteful to make grants when the practitioner certifies (in effect) that the sick man's recovery will be prejudiced or delayed by his remaining at home.

CONCLUSION.

I have endeavoured to show how the infirmaries can be rendered more useful after transfer, which I regard as practically certain. Dr. C. M. Wilson intimated in his opening remarks that there is some risk of the policy with reference to the infirmaries being settled to meet political exigencies. I incline to the opinion that a well-considered scheme prepared by the profession, in consultation with the officials, will be preferred by the public to a scheme prepared by politicians based on theoretical considerations. I think we may claim first that we know the medical necessities of the people, and, secondly, that we still possess their confidence.

AN INVESTIGATION OF THE
CAUSE AND RELIEF OF PAIN IN GASTRIC ULCER.*

BY E. P. POULTON, M.A., M.D. OXON., F.R.C.P. LOND.,
BEIT MEMORIAL RESEARCH FELLOW; ASSISTANT PHYSICIAN, GUY'S HOSPITAL.

THE object of the present communication is to show that an important element in the pain of gastric ulcer is due to distension of the stomach, and can be abolished by reducing the intragastric pressure. Two methods have been adopted in this investigation: 1. A fine rubber tube similar to that used for withdrawing stomach contents in the fractional test-meal method is passed into the stomach. There is some lead in the lower end of the tube, so that it can be localised by means of X rays. Air or oxygen is passed into the stomach through the tube from a reservoir connected with a water manometer, so that the pressure exerted by the air current can be measured. The patient is asked to describe his sensations, whether of fullness or pain, while his stomach is being distended. 2. The patient is asked to pass a similar tube into the stomach when pain is experienced, and in many cases the pain is relieved within a few minutes by release of pressure. The tube should contain a series of holes extending from its end in the stomach upwards as far as the cardiac orifice. Stomach contents may be regurgitated through the tube. The gastro-duodenal tube is a modification of the gastric tube. It connects the stomach with the duodenum, so that pressure is equalised through the pylorus. It is about 2 feet long, and contains holes about 1½ inches apart throughout its length. Both ends are made opaque to X rays by means of short pieces of thick lead fuse wire placed inside the tube between glass beads (in order to keep the digestive juices away from the lead) and securely fastened with silk. To one end of the tube is attached a piece of silk about 27 inches long. The end of the tube not attached to the silk is passed into the stomach, and it then usually passes quite readily through the pylorus. The upper end of the tube is then anchored in the stomach 22 inches from the lips by means of the silk, which can be fastened round the ear or round a dental plate or pinned on the dress. The position of the tube can easily be determined by skiagraphic examination after the stomach has been outlined with a little barium sulphate suspension. It is important not to pass this tube too quickly into the stomach, as if the proximal end reaches the stomach before the distal end has reached the pylorus the tube may become tied into a knot and fail to get through at all. The ordinary thin rubber tubing gets readily acted on by the digestive juices, and such a tube does not usually last more than two or three weeks if kept in position most of the time. It should be removed and examined at least once a week. The thicker-walled tube, introduced by Dr. J. A. Ryle for fractional test meals, is much more durable.

At the outset it should be pointed out that it is not claimed at this stage that the use of these tubes should become a general method of treatment for peptic ulcer. The usual methods of medical treatment are most satisfactory, and of these methods rest in bed is possibly the most important of all. In these circumstances pain usually disappears completely, and in several instances the writer has obtained radiographic evidence of the ulcer becoming less, and completely disappearing in a few weeks. His thanks are due to Dr. Lindsay Locke for some of this evidence. This treatment by means of the tubes has been brought forward rather as evidence of his main proposition, that the pain in gastric ulcer is often chiefly due to distension from increased intragastric pressure and as a preliminary to further work on the subject. To show that the other factors concerned with the relief of pain were absent in the cases it should be stated that the patients were mostly out-patients, some of them doing their usual work; that they came up complaining of pain, that they were encouraged as far as possible to take ordinary food, and that to begin with, at any rate, no drugs were given. Later on in some cases olive oil and liquid paraffin were ordered.

Effect of Intragastric Pressure on Gastric Pain.

The effect of intragastric pressure on gastric sensation has been described by Dr. A. F. Hurst,[1] in the case of two healthy people. He passed air into the stomach, using the kind of apparatus already described, with the exception that a mercury manometer was used instead of a water manometer. The latter is, of course, more delicate owing to its wider range of movement. The sensation produced by such means was one of fullness. The stomach then accommodated itself by becoming larger, the pressure fell, and the feeling disappeared, only to return again when the pressure was raised by passing more air into the stomach. Dr. Hurst observed that there was no sensation of pain accompanying the fullness, except when the stomach was suddenly distended with a large volume of gas, as in the case when sodium bicarbonate and tartaric acid were swallowed immediately after one another. He suggested that gastric pain was more commonly produced by the distension of a part of the stomach, for instance, at the pyloric end, when the active peristaltic wave is on the point of forcing some of the stomach contents through the pylorus. The present observations point to the general intragastric pressure as being of considerable importance in the production of pain in gastric ulcer. Exactly the same variation in the feeling of fullness as that described by Dr. Hurst has been noticed many times in the present series of observations; and in cases where there was reason to believe that no active ulceration was present a sensation of fullness was described, but no pain.

CASE 1.—G. W., a woman, aged 36. In Guy's in 1918. X ray: Tender lesser curvature projection with constriction of greater curvature. The projection had disappeared by the end of her stay, but the constriction remained. Nov. 22nd, 1920: Patient had been free from symptoms for some months. X ray: Midgastric constriction seen with slight tenderness on lesser curvature. There was probably cicatrisation present. Gastric pressure test: 500 c.cm. passed in at 12 cm. pressure. No effect. Another 500 c.cm. were then passed in the pressure, gradually falling to 8 cm. A sensation of fullness noticed but no pain at all. At the end it was seen that the tube had penetrated into the lower compartment of the stomach. Both compartments were much dilated.

CASE 2.—N. B., a woman, aged 51, under the care of Dr. H. French Indigestion since 30 years old. Attacks of pain in epigastrium and lower down over the umbilicus. Pain is worst if she has wind. When examined she had had no pain at all for six or seven weeks. X ray: Hour-glass stomach with slight tenderness on pressure at the site of the constriction on the lesser curvature. The tube when passed was entirely in the upper compartment of the stomach. Gastric pressure test: 400 c.cm. passed in at 20 cm. pressure. Feeling of distension relieved by eructation, no pain at all. Operation by Mr. C. H. Fagge a few days later. Cicatricial hour-glass stomach found, with thickening at pylorus. On opening stomach for gastroplasty the scar of a healed ulcer was seen on the lesser curvature at the site of the constriction.

---

* A paper read before the Medical Section of the Royal Society of Medicine on Jan. 25th, 1921. The expenses of this investigation were defrayed by a grant from the British Medical Association.

CASE 3.—D. R., a woman, aged 30. Since 24 years old she has complained off and on of fullness of stomach and nausea, and difficulty in bringing up wind, with dull pain and tenderness in epigastrium. She is greatly relieved by a belt. X ray: Stomach dropped and atonic; lesser curvature below iliac crest. Stomach empty after 4½ hours. No evidence of ulcer. Gastric pressure test: 110 c.cm., and later 330 c.cm., of air introduced at 6 cm. pressure. Feeling of fullness to the right of the umbilicus, and wind eructated with much relief. No pain experienced at all. She had been resting in bed and her symptoms had greatly improved before the test was carried out.

In another case complaining of hunger pains where there was X ray evidence of duodenal ulcer the introduction of 300 c.cm. at 20 cm. pressure into the stomach caused much distension, but no pain. This is to be expected, since the ulcer would not be affected by the stretching of the stomach wall. Sixteen cases have been examined by this method (Table I.), in all of which there was *good* evidence of active ulceration in the stomach, not only from the description of the symptoms, and often from the presence of occult blood in the fæces, but from skiagraphic examination. The criterion of an ulcer has been taken to be the appearance of a projection from the stomach shadow, usually on the lesser curvature (or sometimes an irregularity in the neighbourhood of the pylorus), which is constant in position and tender on pressure. Occasionally *no* projection was seen, but localised tenderness made the diagnosis probable. When there are cases of this rather doubtful nature in a group their number is indicated by the bracket in the second column. When air was passed into the stomach these patients experienced a feeling of fullness, but in addition their characteristic pain was noticed, and this disappeared on again releasing the pressure. Care was taken in performing the test to ask the patient whether the distension experienced was greater than they had ever felt before. The reply always was that on previous occasions they had experienced much greater distension than was felt at the time of the inflation.

TABLE I.—*Examination of 16 Cases of Active Ulceration in Regard to the Presence or Absence of Pain on Distending the Stomach with Air.*

Position of ulcer.	No. of cases.	Increased pressure in stomach pain = +		Notes on cases with no pain response (−)
Lesser curvature.	8	7 +	2 −	*One case + − on* different occasions.
L. c. acute.	(1)	1 +		—
L. c. and gastro-jejunostomy.	2	2 +	1 −	One case healing.
Stomach, near pylorus.	3 (1)	2 +	1 −	One case showed temporary improvement.
Pylorus.	2	2 +		—
—	16	14 +	4 −	—

(1) X ray; *localised tenderness only present.*

Of the 16 cases examined, 14 described the onset of their characteristic pain in addition to the feeling of fullness, though the pressure at which this occurred was very variable. The following cases show this in detail.

CASE 4.—J. F., a man, aged 40. November, 1919: Pain in epigastrium 30 minutes after a meal. Feeling of distension and vomiting. Symptoms continued off and on till Oct. 1st, the pain between June and October being described as unbearable. X ray: Small tender projection on lesser curvature. Stomach contents contain blood. Occult blood in fæces. Gastric pressure test: On two occasions positive, pain being noticed in middle line above umbilicus; on one occasion negative. About 200 c.cm. of air passed in at 20 cm. pressure. Gastric tube given on Oct. 1st, and a gastro-duodenal tube later. Relief from pain and flatulence. Patient prefers the g.-d. tube, and only uses the g. tube if he gets attack of pain. Jan. 7th, 1921: Has not been so well for three weeks, but has not been up to report: His tubes have been perished and the g.-d. tube broke away 10 days ago. X ray shows small projection still present. Jan. 21st: Has had g.-d. tube for last week, and has had no attack of pain, except on one [illegible]

CASE 5.—M. C., a woman, aged 44. Dyspepsia when 18 and nearly continuously since then. Pain in epigastrium and beneath left costal margin. Perforation of gastric ulcer on April 20th, 1920, and pain and vomiting were specially severe for some weeks before this. Ulcer stitched up and gastro-jejunostomy performed. Has been ill again the last two months. X ray: Gastro-jejunostomy acted well. Tender projection on lesser curvature of stomach. Food does not leave by pylorus. Stomach empty in five hours. Test meal: No free HCl in stomach contents. Dec. 2nd: Gastric pressure test: 150 c.cm. at 10–15 cm. pressure. Pain beneath left costal margin disappearing on releasing pressure. On Dec. 15th 400 c.cm. passed into stomach; a *feeling of distension but no pain.* She is better, but has been lying in bed. Relief from g. and g.-d. tube, the latter seen in position, passing through gastro-jejunostomy opening. Jan. 13th, 1921: Ulcer projection cannot be seen, but the spot is still tender. She has had no pain since Dec. 15th, and has been up all the time on ordinary food.

CASE 6.—P. F., a man, aged 61. Ten years' history of indigestion. 1916: X ray: 2/3 of barium in stomach at end of seven hours. Operation: Gastro-jejunostomy for peptic ulcer. I saw him for return of symptoms November, 1917, till July, 1918. Much ærophagy. I saw him again March, 1920, and he was much worse. June, 1920: Second operation. Ulcer found on lesser curvature adherent to liver. Stomach opened and ulcer cauterised. Operation unsuccessful in relieving symptoms. October: X ray: Tender projection on lesser curvature. Stoma acts quite well. Stomach contents bile-stained, with absence of free HCl. Gastric pressure test: 250 c.cm. at 10 cm. pressure which showed great variations. Characteristic pains observed. G.-d. tube would not pass through the stoma. *He gets some, but not complete relief* from gastric tube. This patient suffers much from aerophagy, taking air into the stomach by repeated attempted eructations. On one occasion when he had pain the stomach was noticed much distended without any air being introduced. The manometer attached to the g. tube registered *big excursions,* the pressure reaching up to 24 cm. on respiration, while it was 10 to 14 cm. when the breath was held. The tube was kept attached to the manometer for a quarter of an hour and no difference in the pain was felt. The pain felt a bit easier three minutes after disconnecting *so as to allow the air to* escape by the tube, and had completely gone in 23 minutes.

CASE 7.—E. C., a woman, aged 31. In Guy's two years ago for gastric ulcer; pain half an hour after meals. September, 1920: Tender mid-gastric projection on lesser curvature. Nov. 19th: Gastric pressure test 500 c.cm. at 10 cm. pressure. Fullness and characteristic pain in epigastrium and in her back. Jan. 14th, 1921: She gets relief from pain and wind from the g. tube. During the last week has used it every morning for half an hour.

CASE 8.—A. J., a man, aged 31. Pain in epigastrium and round umbilicus for five years off and on. Two previous X ray examinations not very definite. *Was previously in Guy's as an* in-patient. X ray: Tenderness definitely marked on the stomach side of pylorus. Fæces: Occult blood present. Stomach empties very rapidly. Gastric pressure test: 200 c.cm. at 10 cm. Typical pain in epigastrium which disappeared on releasing pressure. Relief from g. and g-d. tubes. Sometimes after they are not effective he has pulled them up and found them blocked.

Of course, the pressure of the gas entering the stomach is only a very rough way of gauging the intragastric pressure, and it is intended to carry out further observations by means of a more accurate method. Of the two cases who did not feel any pain one showed temporary improvement in his symptoms at the time of the observations, but relapsed later. Two of the other cases failed to respond, when they were improving. One case (l.c. acute) is of particular interest as he is a medical man. After an attack of diarrhœa he suddenly developed pain beneath the left costal margin, coming on one and a half hours after meals, and made worse if ordinary food were taken. This pain had lasted for three weeks. X rays showed that the lesser curvature of the stomach was tender in one spot, but it was doubtful if a projection was seen. The stomach was normal in position. It was thought that he probably had an acute ulcer. Pain was absent when the tube was passed. 200 c.cm., and later 300 c.cm., of air were passed in at 20 cm. pressure. He noticed the appearance of his characteristic pain as well as a feeling of fullness. After the examination, possibly on account of the large amount of barium sulphate given, his pain was permanently arrested.

It might be thought that the gastric-pressure test would provide a valuable means of *diagnosing active* ulceration of the stomach, but, although a negative result may be of value in excluding such a condition, it does not follow that a positive result means a gastric lesion. Thus, in the case of Mary B., aged 65, under the care of Dr. French, complaining of abdominal pain, the latter was definitely increased on passing 100 c.cm. into the stomach and was lessened again by relieving the tension. *Operation disclosed a carcinoma of the* pancreas, and the post-mortem showed that the stomach was normal, no trace of any acute or chronic ulcer being seen.

With regard to the second method of investigation—viz., the relief of pain on passage of one or other of the tubes—observations have been made on 16 cases. They are summarised in Table II., and certain illustrative cases are described more fully. It is not claimed that complete relief from pain was obtained in all the 18 cases of Column 8. There may be other factors in its causation. But the patients were satisfied that the tubes were beneficial and that they often prevented the onset of pain. Of the three unsuccessful cases one was unreliable, since every two or three days fresh pains appeared in different parts of the body. One was a very advanced case of saddle-shaped ulcer of the lesser curvature found at operation; gastro-jejunostomy was not done. He disliked the gastric tube intensely, and received no benefit from it. The other patient also disliked the tube and has since improved without it.

TABLE II.—*Examination of 16 Cases of Active Ulceration in Regard to the Relief of Pain on Passing a Tube.*

Position of ulcer.	No. of cases.	Relief of pain.	Unsuccessful.
Lesser curvature.	8 (1)	6	Two cases disliked tube; one was very advanced.
L.c. and gastro-jejunostomy.	2	2	—
Stomach, near pylorus.	4 (1)	3	? 1 unreliable.
Pylorus.	2 (1)	2	—
—	16	13	—

(1) X ray; localised tenderness only present.

Effect of Intragastric Pressure on Continuance of Ulceration.

So far it has been shown that pain in gastric ulcer can be produced by only moderately distending the stomach, and can be relieved by releasing the pressure. Is there any evidence that gastric pressure is responsible for the continuance of the ulcer? At present the cause of chronic gastric ulcer is a profound mystery. Clinical evidence is naturally hard to assess, and particularly in the case of gastric ulcer, which so often tends to heal of its own accord, at any rate for the time being. One of the out-patients has now for two months completely lost her gastric pain, which had recurred in July, 1920, after she had been successfully treated for it in hospital by rest in bed. The fæces now contain no occult blood. The other out-patients say they are better. Of 5 cases at present undergoing treatment in hospital 3 seem to have lost their pain completely; the other 2 still get some attacks. It is early to draw conclusions.

It will, however, be worth while to consider other evidence bearing on this point. Bolton[2] found experimentally that if gastro-toxic serum was used it was the HCl of the stomach that was responsible for the formation of the acute ulcer, which could be completely prevented if the stomach contained alkali. It is reasonable to look upon the HCl as an important factor in the causation of human peptic ulcer. But Bolton found it was not at all easy to produce an experimental chronic ulcer. The acute ulcer healed readily whether the stomach contained food soaked with acid or alkali, whether it was infected by bacterial cultures, or whether the animal was rendered anæmic. The only way to hinder the healing was to give meat instead of milk, or to produce artificially some degree of pyloric stenosis. These factors would both tend to cause a retention of food in the stomach; but they would also both lead to increased gastric pressure.

Bolton describes the shape of his experimental ulcers as that of a funnel or some modification of a funnel. Ulcers as seen by X rays often appear as funnel-shaped projections, and at other times present the form of sacs. These shapes can be explained on the intragastric pressure hypothesis; but Bolton's explanation, that they are due to action of the gastric juice, is not very satisfactory, because the latter would act evenly over the whole surface and not eat away more in the middle of the ulcer.

Bolton describes the experimental ulcer which is adherent to the pancreas as having a flat base, and suggests that this is due to some special resisting power on the part of the pancreas. But such a hypothesis is unnecessary if intragastric pressure is the cause, since the pancreas is a firm organ, while in most other positions the ulcer projects out against yielding coils of intestine. Gastric ulcers at post-mortem are usually described as having flat bases; but it does not follow that this is their shape during life inside the body.

The hydrochloric acid of the stomach has been considered to be the cause of chronic gastric ulcer, but while its concentration is usually increased in pyloric and duodenal ulcers, it may be quite low with ulcers in the body of the stomach, as has been pointed out by Bolton. Again, in two cases of ulcer on the lesser curvature, one recurring after gastro-jejunostomy, the test meal showed absence of free HCl, while in these cases a rise of pressure was obtained on passing air into the stomach, showing that the opening did not always remain patent. In both cases, however, food was seen to leave the stomach rapidly (see Cases 5 and 6).

It is possible to explain the beneficial effects of gastro-jejunostomy by the release of pressure, but it is not generally realised with what dramatic suddenness complete relief from pain may be achieved by this operation. In two cases of chronic ulcer of the lesser curvature, one associated with considerable gastric delay, the patients complained of intense pain while at rest in bed, in spite of dieting, and it was only possible to relieve this by morphia. Mr. R. Davies-Colley performed gastro-jejunostomy. Pain was completely relieved at once. It was in reflecting on these cases, and after a conversation with Mr. E. G. Slesinger about his work with Dr. Hurst, that the possible use of gastric and gastro-duodenal tubes suggested itself to the writer.

The perforation of a gastric ulcer may be due to acute distension of the stomach (Case 5). The patient states that for some weeks before perforation occurred she suffered from the most severe pains with wind, culminating in the final excruciating paroxysm when the ulcer perforated.

In 1918 the writer performed a post-mortem examination on a patient who had died of pneumonia about three weeks after an operation for chronic gastric ulcer on the lesser curvature. In this case the ulcer had been excised but no gastro-jejunostomy had been done, and the pylorus had been left intact. At the post-mortem examination it was found that the stitches had given way, and that the ulcer had re-formed in the middle of the incision. This can be explained on the hypothesis that the intragastric pressure had not been relieved.

Lavage has been frequently performed with benefit in the past for gastric ulcer. In a South African patient in whom the presence of gastric ulcer was proved by means of X rays Dr. Fonché prescribed lavage. The patient subsequently informed him that she found it unnecessary to wash out the stomach. The presence of the tube alone was quite enough to abolish the pain.

The writer wishes to express his best thanks to Dr. French and to the authorities of Lambeth Infirmary for facilities for investigating certain of their cases.

Conclusions.

1. An important element in the pain of gastric ulcer is due to distension of the stomach, and can be relieved by means of gastric and gastro-duodenal tubes.

2. Some evidence has been brought forward that chronic gastric ulcer is due to intragastric pressure.

BRISTOL DISPENSARY.—The annual report of the Bristol Dispensary states that during 1920 the patients treated reached the record number of 10,324. The expenditure unfortunately exceeded the income. Dr. R. Shingleton Smith, honorary consulting physician to the institution, whose active interest has for many years been unstintingly placed at the service of the charity, has resigned from the committee owing to ill-health.

THE INDUCTION OF ABORTION.

BY SIR JOHN PHILLIPS, M.A., M.D. CANTAB., F.R.C.P. LOND.,

HONORARY PHYSICIAN TO H.M. QUEEN MARY; CONSULTING OBSTETRIC PHYSICIAN TO KING'S COLLEGE HOSPITAL; AND EMERITUS PROFESSOR OF OBSTETRICS IN KING'S COLLEGE.

THE induction of abortion, by which may be understood the interruption of pregnancy before the viability of the child has occurred, is a subject which has been widely debated and concerning which many diverse views have been, and still are, held. On the one hand, we have those who consider that the operation should under no circumstances be performed; on the other, there are those who are of opinion that there are a certain number of cases in which the operation, repugnant as it is to the conscientious practitioner, is not only indicated, but is absolutely necessary to save maternal life.

Definition.

As a preliminary, it would be as well to make an accurate definition of the word *abortion*, which is apparently derived from the Latin word *abortus*, the past participle of the verb *aboriri* (to fail to appear or fail to be born).[1] The word *abortion* is generally conceded as including *all* cases where the termination of labour occurs before the twenty-eighth week. This period may be conveniently subdivided into cases occurring before the twelfth week—i.e., just before the complete formation of the placenta, and usually termed "embryonic" abortion, and those that take place from the twelfth to the twenty-eighth week, termed "fœtal" abortion, or miscarriage.[2] In this paper I have preferred to use the word abortion as an inclusive term for both groups.

My own experience of this operation during a period of 35 years of private practice has been limited to 57 cases, a summary of which I append: acute albuminuria, 18; glycosuria, 2; uncompensated cardiac disease, 11; incoercible vomiting, 15; acute salivation, 1; chorea, 1; placenta prævia, 6; cancer of the breast, 3. In all these cases a consultation was held, and complete agreement was reached that artificial abortion was the best, indeed the only, course to pursue to save maternal life. No maternal mortality occurred in this series of operations.

In Dr. W. (later Sir William) Priestley's list of indications for abortion[3] he mentions marked pelvic deformity; this pathological condition is now, of course, better treated by the performance of the improved Cæsarean section at or about term.

Albuminuria.

In all these cases very much the same train of symptoms showed themselves—headache, difficulty of vision, and, later on, puffiness of face, hands, and feet, with an increasing amount of albumin and casts. To these were added, in two cases, signs of mental instability, which somewhat hastened interference. All were treated in the usual way—by rest, diet, and the various drugs employed in these cases, but rapid increase in the disease took place. Fortunately, in none of them did any convulsions occur; the albumin disappeared within 14 days of operation in 12 cases; in the remainder it persisted for some weeks. In three instances commencing molar changes were discovered, and in three others areas of thrombosis were present in the placenta.

Glycosuria.

Induction was carried out in these cases for rapid increase in the already existing disease, emaciation and great thirst being the two marked symptoms, with red tongue and sordes round the mouth. Obviously, the pregnancy had a stimulating effect on the formation of the sugar, and although treatment was prolonged in both cases until the end of the fifth month it was clearly unsafe to allow the pregnancy to go on longer.

Uncompensated Cardiac Disease.

The time of selection for induction of abortion in this class of case is very difficult to determine. In all those in which it was performed dyspnœa, œdema of the feet, and slight albuminuria, with duskiness of the face and purplish colour of the lips, were present before the completion of the fourth month. Several of the patients were invalids before the pregnancy began. The pathological conditions necessitating interference were as follows: double aortic disease in four instances, aortic and mitral stenosis in five, and mitral regurgitation in two. In all of them relief of the symptoms followed the operation; in four, however, the natural progress of the disease led to a fatal result after a lapse of about 12 to 15 months.

Incoercible Vomiting.

This complication I have found to be one of the commonest reasons for induction of abortion. All the cases commenced with nausea and sickness before eight weeks of the pregnancy had passed. In all of them the course run was fairly acute, and induction was found necessary before the twelfth week. The symptoms of gravity which led me in each case to recommend the operation were a slightly rising temperature at night, a peculiarly anxious look in the face, rapid wasting, and a dry reddish tongue. In nine cases the sickness ceased within a week of the operation, but in the remaining six it persisted in a mild form until menstruation appeared. In all of them every kind of local and general treatment was tried, including the application of strong tincture of iodine to the cervix and the insertion of cocaine pessaries. I believe that the great danger in the treatment of these cases is delaying interference, and, although I did not have the misfortune to lose a case, three of them would certainly have been the better for induction a week earlier. All these cases were under 30 years of age, and all primigravidæ except two, in which latter the operation had to be performed twice for the same ailment; in five others pregnancy again occurred, but although the sickness was severe it did not call for interference. Slight albuminuria was present in 6 of the 15. In 2 cases some old hæmorrhage was present in the decidua, but in the remainder no pathological condition could be found. In 12 cases the uterus was in normal situation and anteflexed to a greater or less degree; in the remaining 3 retroflexion was present; in 2 of the latter re-position and the insertion of a pessary failed to relieve the symptoms; in the other, anterior suspension of the uterus was carried out after the first pregnancy, but in spite of the operation the sickness was as severe as before.

Acute Salivation.

During the early months of pregnancy and almost synchronous with nausea and vomiting, a more or less amount of salivation is very common. As a rule it ceases with the sickness and does not often incommode the patient to any serious extent, but on rare occasions it leads to such a serious state of health as to necessitate interference. I have only met with one such case. The patient, aged 30, was a IV.-para, and of highly nervous temperament, but otherwise enjoying good health. Her first pregnancy was quite normal. In the second a parovarian cyst was removed in the third month, when salivation commenced and continued throughout the pregnancy. Salivation also complicated the third pregnancy, which resulted in a miscarriage. In the fourth there was profuse salivation throughout, and confinement was rapid and easy. In the fifth salivation was much more profuse than formerly, and a rough measurement on two occasions showed a secretion of over two quarts in 24 hours. Examination of the secretion gave no abnormal reaction, except excess of water; no albumin was present. The uterus, which was retroflexed, was replaced and supported by a pessary, but without benefit. Sleeplessness and rapid loss of flesh were prominent features of the case, and, finally, commencing mental disturbance rendered induction necessary at the tenth week. Salivation went on for 14 days continuously after the abortion and recurred at every menstrual period afterwards for several months.

Chorea.

This patient, a young primigravida, aged 25, had when aged 15 suffered from an acute attack of chorea, with rheumatic symptoms, but uncomplicated by any cardiac disease. Subsequent to this illness she was subject under excitement to a certain amount of twitching of the face and hands; otherwise she was in perfect health. Shortly after marriage, when she had missed three periods, distinct choreic movements began, champing of the mouth and slobbering being the prominent symptoms. As in the late Dr. M. Handfield-Jones's case,[4] no medicinal treatment appeared to have any effect upon the complication. Her mental condition remained quite clear until about the eighteenth week, when decided symptoms of acute mental disturbance presented themselves. Induction of abortion was therefore carried out by means of rapid dilatation and the insertion of a de Ribes bag, control of her limbs and body being maintained by the use of blankets and sheets. Immediately after the expulsion of the ovum all bad symptoms rapidly disappeared, and although the choreic movements lasted for nearly six weeks and recurred for nearly a year under any excitement, she ultimately made a good recovery.

Placenta Prævia.

In all six cases profuse hæmorrhage, without warning, was the urgent symptom, and the pathological condition was suspected. In three of the cases the position of the placenta was actually diagnosed from the sixteenth to the eighteenth week, owing to a certain amount of cervical dilatation being present, and induction of abortion (fœtal variety) was at once carried out, a small de Ribes bag being used as the provocative agent.

Cancer of the Breast.

Of late years it has been urged by surgeons that in a woman who has had a breast removed for cancer it is most undesirable to allow the remaining organ to be stimulated by the onset of pregnancy. Although I am not in full accord with this course, I think it is a proper proceeding to induce abortion in the case of a young woman with a rapidly growing form of carcinoma, but it must be done in the earlier stages of pregnancy to be of any efficacy. I have carried this out in three instances, but I think that the pros and cons in every case should be carefully weighed and no general rule followed.

Mental Aberration.

There are two classes of case which require well-balanced consideration as to the best course to pursue—namely, mental aberration and a retroflexed impacted gravid uterus. Mental aberration is even more important to the alienist than to the obstetrician, and when it occurs during the early stages of pregnancy it is chiefly due to the result of exhaustion from emotional shock, anxiety, or physical disease, with consequent insomnia. I have been in the habit of dividing such cases into three groups: 1. "Border-line" before marriage, which, on pregnancy ensuing, very soon develop definite symptoms. 2. Those who, though perfectly healthy in all respects before marriage, have been subjected to severe nerve stress, and on becoming pregnant develop mental symptoms. 3. Those who, though normal mentally and with a good family history, on becoming pregnant develop an exhausting illness, such as chorea, uræmia, obstinate vomiting, or acute salivation, and begin to show signs of impending mental disturbance, of which they themselves are cognisant. I entirely agree with Sir Maurice Craig[5] that if induction of abortion is to be carried out in these cases it should be done early—that is, before the tenth or twelfth week of pregnancy (embryonic abortion). There is no doubt that induction may easily be deferred so long that the patient's prospect of recovery is much diminished. Dr. Craig further advocates the free use of sedatives, opiates excepted, up to the time of abortion or delivery and for some time subsequently. It is difficult to generalise on the treatment of these cases, and each one should be considered on its merits.

Retroflexed Impacted Gravid Uterus.

This particular complication is mentioned by Dr. Priestley in his paper[6] as a reason for abortion; at the same time he adds: "It should, nevertheless, be distinctly understood that the mere existence of this form of displacement and the impossibility of immediately reducing it does not necessarily call for induction of abortion; only when it gives rise to grave symptoms, imperilling the life of the patient, is it permissible." It must be remembered that a large number of cases which apparently are permanently impacted become spontaneously reduced as the pregnancy progresses. Moreover, in Oldham's well-known case labour[7] at full time was terminated successfully with the uterus still in the impacted retroflexed condition. The symptoms accompanying this complication are said to be very grave, but I have never personally met with a case in which interference was necessary, nor can I see how induction of abortion could be carried out with a cervix pressed firmly into an œdematous anterior vaginal wall, preventing the introduction of any instrument into the uterus. Should such a case be encountered I believe the only course is to open the abdomen and lift the pregnant fundus out of the pelvic cavity. I have seen two cases in which, the abdomen having been opened for what was supposed to be an impacted ovarian cyst complicating pregnancy, it was found to be quite easy to raise the pregnant fundus out of the pelvic cavity.

Other Conditions.

There are certain complications of pregnancy which are thought by a limited number of authorities to indicate induction of abortion. I allude to phthisis, general tuberculosis, epilepsy, conditions leading to paraplegia, and, finally, cases in which previous labours have resulted in the birth of congenitally deformed or mentally deficient children.

At a meeting of the Obstetrical Society in 1890 Dr. William Duncan read a paper on "Should Pregnancy be Terminated Prematurely in Cases of Phthisis?"[8] In this he related a case in which he induced abortion by the rapid method in a woman with phthisis who was eight to ten weeks pregnant. In the discussion which followed no less than nine teachers of obstetrics in London hospitals gave their views on the advisability of such a proceeding, and all, without exception, expressed disapproval, the chief argument used being that there was no proof at present forthcoming to show that the onset of pregnancy in any way accelerated the progress of the pulmonary disorder. I think the majority of observers will be in accord with this statement, and I, personally, have never met with a case in which I could see that any benefit could possibly arise by interference with the pregnancy. The same may be said of general tuberculosis.

With regard to epilepsy, I do not think there is any distinct evidence that the fits become more frequent or more severe in character as the result of the onset of pregnancy, and I should therefore consider this variety of case as one in which it would not be desirable to interrupt the course of pregnancy.

Concerning paraplegia, experience is against interference, and this opinion is amply supported by Dr. Amand Routh's paper,[9] in which he describes a case which was under his observation during the latter eight weeks of pregnancy and during the labour and puerperium. There was no diversion from the normal throughout.

Lastly, in regard to congenitally deformed and mentally deficient children, I think a similar opinion may be expressed. The most marked instance which came under my notice was one in which the prospective mother had a peculiar deformity of the fingers, both

THE INDUCTION OF ABORTION.

BY SIR JOHN PHILLIPS, M.A., M.D. CANTAB., F.R.C.P. LOND.,

HONORARY PHYSICIAN TO H.M. QUEEN MARY; CONSULTING OBSTETRIC PHYSICIAN TO KING'S COLLEGE HOSPITAL; AND EMERITUS PROFESSOR OF OBSTETRICS IN KING'S COLLEGE.

THE induction of abortion, by which may be understood the interruption of pregnancy before the viability of the child has occurred, is a subject which has been widely debated and concerning which many diverse views have been, and still are, held. On the one hand, we have those who consider that the operation should under no circumstances be performed; on the other, there are those who are of opinion that there are a certain number of cases in which the operation, repugnant as it is to the conscientious practitioner, is not only indicated, but is absolutely necessary to save maternal life.

Definition.

As a preliminary, it would be as well to make an accurate definition of the word *abortion*, which is apparently derived from the Latin word *abortus*, the past participle of the verb *aboriri* (to fail to appear or fail to be born).[1] The word *abortion* is generally conceded as including all cases where the termination of labour occurs before the twenty-eighth week. This period may be conveniently subdivided into cases occurring before the twelfth week—i.e., just before the complete formation of the placenta, and usually termed "embryonic" abortion, and those that take place from the twelfth to the twenty-eighth week, termed "fœtal" abortion, or miscarriage.[2] In this paper I have preferred to use the word abortion as an inclusive term for both groups.

My own experience of this operation during a period of 35 years of private practice has been limited to 57 cases, a summary of which I append: acute albuminuria, 16; glycosuria, 2; uncompensated cardiac disease, 11; incoercible vomiting, 15; acute salivation, 1; chorea, 1; placenta prævia, 6; cancer of the breast, 3. In all these cases a consultation was held, and complete agreement was reached that artificial abortion was the best, indeed the only, course to pursue to save maternal life. No maternal mortality occurred in this series of operations.

In Dr. W. (later Sir William) Priestley's list of indications for abortion[3] he mentions marked pelvic deformity; this pathological condition is now, of course, better treated by the performance of the improved Cæsarean section at or about term.

Albuminuria.

In all these cases very much the same train of symptoms showed themselves—headache, difficulty of vision, and, later on, puffiness of face, hands, and feet, with an increasing amount of albumin and casts. To these were added, in two cases, signs of mental instability, which somewhat hastened interference. All were treated in the usual way—by rest, diet, and the various drugs employed in these cases, but rapid increase in the disease took place. Fortunately, in none of them did any convulsions occur; the albumin disappeared within 11 days of operation in 12 cases; in the remainder it persisted for some weeks. In three instances commencing molar changes were discovered, and in three others areas of thrombosis were present in the placenta.

Glycosuria.

Induction was carried out in these cases for rapid increase in the already existing disease, emaciation and great thirst being the two marked symptoms, with red tongue and sordes round the mouth. Obviously, the pregnancy had a stimulating effect on the formation of the sugar, and although treatment was prolonged in both cases until the end of the fifth month it was clearly unsafe to allow the pregnancy to go on longer.

Uncompensated Cardiac Disease.

The time of selection for induction of abortion in this class of case is very difficult to determine. In all those in which it was performed dyspnœa, œdema of the feet, and slight albuminuria, with duskiness of the face and purplish colour of the lips, were present before the completion of the fourth month. Several of the patients were invalids before the pregnancy began. The pathological conditions necessitating interference were as follows: double aortic disease in four instances, aortic and mitral stenosis in five, and mitral regurgitation in two. In all of them relief of the symptoms followed the operation; in four, however, the natural progress of the disease led to a fatal result after a lapse of about 12 to 15 months.

Incoercible Vomiting.

This complication I have found to be one of the commonest reasons for induction of abortion. All the cases commenced with nausea and sickness before eight weeks of the pregnancy had passed. In all of them the course run was fairly acute, and induction was found necessary before the twelfth week. The symptoms of gravity which led me in each case to recommend the operation were a slightly rising temperature at night, a peculiarly anxious look in the face, rapid wasting, and a dry reddish tongue. In nine cases the sickness ceased within a week of the operation, but in the remaining six it persisted in a mild form until menstruation appeared. In all of them every kind of local and general treatment was tried, including the application of strong tincture of iodine to the cervix and the insertion of cocaine pessaries. I believe that the great danger in the treatment of these cases is delaying interference, and, although I did not have the misfortune to lose a case, three of them would certainly have been the better for induction a week earlier. All these cases were under 30 years of age, and all primigravidæ except two, in which latter the operation had to be performed twice for the same ailment; in five others pregnancy again occurred, but although the sickness was severe it did not call for interference. Technique.

In spite of antiseptics and modern improvements the induction of abortion must be considered as an operation attended by definite danger. The chief risks are septicæmia, sapræmia, septic peritonitis, deep laceration of the cervix, followed by para- or peri-metritis, perforation of the uterine wall, thrombosis, and embolus (blood or air), and the operation may often be followed by a long period of ill-health but without any definite symptoms. The procedure differs somewhat according to the period of pregnancy at which it is performed, either before the twelfth week (embryonic abortion), or from the twelfth to the twenty-eighth week (fœtal abortion).

There is no doubt that every precaution must be used in the operation, and the former common custom of producing abortion by the introduction of a uterine sound, or by injecting tincture of iodine or other fluids, is attended with the greatest risks and cannot be sufficiently condemned.

Early cases.—The patient should be placed in the lithotomy position, the cervix pulled down with a volsellum, and, according to the operator's choice, one or more laminaria tents inserted into the cervix, or rapid dilatation of the cervix carried out with graduated bougies. A pair of polypus or ovum forceps should then be introduced into the uterine cavity, and the whole mass can then usually be removed in one piece. On examination of the removed abortion, should there be any suspicion of a portion of the ovum being left behind, it is better to pass the finger right into the uterus up to the fundus, to be quite sure that the cavity is empty and that no second ovum is present. The operation may be completed by washing out the uterine cavity with tincture of iodine, one teaspoonful to the pint, or swabbing it out with iodised phenol. I do not think, however, that either of these is absolutely necessary. Packing the uterine cavity with sterilised gauze was formerly much in vogue, but is, I think, undesirable. Its object was to produce uterine contraction, but this is better brought about by the injection of pituitary extract or ergot at the end of the operation. Anyone who has smelt the gauze removed from a uterine cavity, even 24 hours after the operation, will have been struck by the often offensive odour which emanates from it.

The question of performing curettage is one on which there is much diversity of opinion. Personally, unless there is some molar change in the ovum, I do not think it should be carried out as routine practice.

More Advanced Cases.

In the more advanced cases I think laminaria tents are usually preferable to rapid dilatation, and after removal of the tent and sufficient dilatation of the cervix I insert a specially made small de Ribes bag, which not only ensures the initiation of labour pains, but in cases of placenta prævia safeguards the patient from the results of hæmorrhage. As an argument in favour of this method I know of no more difficult vaginal operation than the removal of a 16–20 weeks' pregnancy by means of ovum forceps after rapid dilatation. The fœtus has by then attained to considerable size, but is still soft in consistence, with a much-enlarged head attached to the body by an easily torn-through neck, and in delivering the fœtus the head may be left behind; this will often defy removal owing to the difficulty of seizing it with any form of forceps at present devised. Much manipulation is necessary in these cases, and bruising and skin-sloughing may result and some form of sepsis ensue.

BRISTOL MENTAL HOSPITAL.—The Bristol Lunatic Asylum at Fishponds will in future be known as the Bristol M[illegible] Hospital. The institution was opened in 1851, at a [illegible]0,000, and then accommodated 220 patients. It has [illegible]arged on several occasions, and now provides room [illegible]y 1000 patients.

THE INCISION FOR APPENDICECTOMY.

BY NORMAN C. LAKE, M.D., M.S., D.SC. LOND., F.R.C.S. ENG.,

ASSISTANT SURGEON, CHARING CROSS HOSPITAL; SURGEON, QUEEN'S HOSPITAL FOR CHILDREN.

THE technique of operations which are performed very frequently tends to become rigidly stereotyped, and while we all have our eyes open to the advantages of a "set" operation, we are unfortunately often blind to its disadvantages. Since the introduction of the operation for the removal of the vermiform appendix, surgeons have for the most part used either the muscle-splitting incision of McBurney, or the rectus incision of Battle. Of these, the former is the more extensively employed, but there can be little doubt that they are both excellent or they would not have stood the test of time. Nevertheless, such stereotyped operations are often dangerous, in that they lead one to fall into the rut of unconsidered repetition.

Disadvantages of Stereotyped Operations.

There is a kind of "herd instinct" about surgery which lends its moral support to the performance of the classical operations, and often completely overbalances the surgeon's considered judgment of the individual case. For these reasons, if for none other, it is necessary to acclaim the stereotyped operations with a certain amount of reserve. They are magnificent for the teaching of operative surgery, but they are designed for ideal cases with a perfect diagnosis, and, as we all know, such cases are rare.

Higher mathematicians in complicated calculations, where perhaps absolute accuracy is not required, are continually dealing with what is known as the percentage error. In any estimation involving two consecutive calculations, the second of which depends upon the result of the first, it is obvious even to the layman that the percentage error must be roughly equal in both. It would, for instance, be futile to determine the second with absolute accuracy, if the first involved a large percentage error. It seems to me that this mathematical principle can be applied with advantage to the surgical treatment of disease. In this sense the treatment of any condition consists of two parts: (1) the diagnosis; (2) the operative treatment, the latter depending upon and being a function of the former. It therefore becomes necessary to have some idea of the percentage error in diagnosis before any estimate can be formed of the accuracy of any method of treatment.

Percentage Error in Diagnosis.

Opinions vary very considerably as to the percentage error of diagnosis in any disease, and it is, of course, impossible to express in mathematical formulæ something which depends to such a large extent upon the personal skill of individuals. Nevertheless, I am sure that many operations are designed without cognisance being taken of the fact that this error is frequently quite a large one. A well-designed operation should allow the error of diagnosis to be corrected if possible at the time of operation, if this cannot be done then the error of diagnosis is carried on through the treatment and the case is unsuccessful. Where, on the other hand, the error of diagnosis is very small—e.g., herniæ—there is little need to depart from the classical operations. Let us now apply this to the case of appendicitis, always remembering that the percentage error will vary within certain limits according to the skill of the individual surgeon. For this very reason it is no use appealing to personal experience only, if anything like an average figure is to be obtained.

Fortunately, I have had the opportunity of following the work of a number of surgeons both at home and abroad for several years, and during this time I have attempted to form some sort of idea as to the percentage error in their diagnosis of disease, and particularly in appendicitis. To read the current books upon the subject one would be led to think that the percentage error was a small one. Actually, however, I have found quite the reverse to be the case. With this, my personal experience, and that of several of my colleagues to whom I have spoken, agrees. It is true, of course, that the more thoroughly a case is investigated and considered, the smaller this error becomes within certain limits. I am dealing rather with diagnosis as it is usually made than with ideal possibilities; but even in the latter case, when the utmost of care is taken, the percentage error is very much larger than we are inclined to think.

For our purpose the disease may be conveniently divided up into two big groups—the acute and the chronic. As mentioned above, it is impossible to give accurate figures, but roughly the error is 10 per cent. to 20 per cent. in the acute cases, and 20 per cent. to 30 per cent. in the chronic cases. It will be seen that the error is a very considerable one, and under the circumstances it is certainly not very logical to deal with the second part of the treatment—namely, the operation—as if there were no need to provide for eventualities in its performance.

There are some surgeons to whom the word appendicitis is apparently a mere shibboleth: they "diagnose" appendicitis, remove the appendix, and are satisfied. No doubt ever seems to enter their mind as to the accuracy of their "diagnosis" and therefore no doubt as to the efficacy of their treatment. Their incisions reflect this confidence, for they are so designed as to preclude the possibility of any exploration of the abdomen beyond the actual appendix. Fortunately for their peace of mind, if the pain recurs the patient most frequently seeks the advice of some other surgeon who is helped towards the correct diagnosis by the previous failure.

An Alternative Incision.

It is because the error of diagnosis is a large one that I think practically all cases, where it is proposed to remove the appendix, should be regarded in the light of exploratory laparotomies with a suitably designed incision for that purpose. Before departing from the more classical incisions, however, it will be necessary to see that their well-tested merits in many respects are not lost, particularly with regard to the accessibility of the appendix and the strength of the resulting scar. The incision which I now use in the great majority of my cases is neither new nor original, but it appears to meet these demands, while at the same time allowing thorough exploration if necessary. It is a vertical rectus incision passing through the anterior rectus sheath at the junction of inner and middle thirds, the *rectus being retracted out* (this constitutes the essential difference from Battle's incision) and the posterior sheath divided in the same vertical plane as the anterior. The great advantage of this incision over Battle's is, that there is no danger of injuring the nerves entering the rectus sheath at its lateral border, *no matter to what length it* may be found necessary to enlarge the incision, should the diagnosis be at fault.

One feels, therefore, no compunction in extending this incision, knowing that no paralysis of the rectus can occur, and consequently that the abdominal wall will not be permanently weakened. It can easily be objected, *of course, that the general* exploration is obtained at the expense of accessibility of the actual appendix, and to some extent this objection is a valid one. The answer can only be obtained by practical experience of the incision. I have now employed it in about 800 cases, and although it would be unwise to draw any far-reaching generalisations *from* such a small number, they are sufficiently numerous to prove that with good retraction there is very little difficulty in getting reasonable exposure of the right iliac fossa, so that any slight disadvantage arising from this is very much overbalanced by the advantage of being able to correct the error of diagnosis. Incidentally, although some of the cases were done seven years ago, I have not had any cases of secondary hernia brought to my notice even in cases which were drained; they may, of course, have occurred and gone elsewhere for treatment.

The importance of attempting to correct the error of diagnosis in the chronic cases is well illustrated by the following, which have all occurred within the last year.

Two of my medical friends have had their appendices removed for sudden attacks of pain in the right iliac fossa. In both cases the respective surgeons used a small *McBurney's incision, and no attempt was made to correct* any error of diagnosis. In both cases the pain recurred after a short interval, and both patients subsequently passed small renal calculi, since when they have been quite well.

There are a large number of conditions enumerated in the text-books of differential diagnosis, which not only may, but do, frequently so closely resemble appendicitis that the most experienced observer cannot with certainty distinguish them. The cases given above are not by any means unique, they occur to every surgeon of experience now and then, and it is surely more honest to recognise the error than to bury one's head in the sand of perfection. Before leaving the chronic cases to consider the rather controversial acute cases I should like to instance one or two further cases in which a more general incision would, in all probability, have demonstrated the diagnosis at the first operation.

A young lady suffering from attacks of pain in the right iliac fossa was subjected to appendicectomy without any relief to her condition. At a subsequent operation undertaken for the relief of "adhesions" it was discovered that her real trouble was a chronic tube on the right side.

A man, aged 36, was similarly operated upon without relief. He died later of a retroperitoneal sarcoma, which would most certainly have been discovered at the operation had the incision been suitably placed.

A case of osteo-arthritis of the spine with referred pain on the right side was subjected to appendicectomy, again without relief. The diagnosis was changed to "gall-stones" and a second operation undertaken for the relief of this. It is obvious that the second operation was not necessary, for a complete exploration of the abdomen the first time would have indicated that the pain could not be explained by any intra-abdominal condition.

It is of great interest to note that in all of the above cases chronic appendicitis was actually present; it does not follow logically, however, that the appendix is necessarily the cause of the patient's present illness. At the same time, these cases illustrate how essential it is, even when the appendix shows obvious signs of disease, to find out whether any other condition exists coincidently.

The Risk of Spreading Infection.

When we come to consider how this affects the case of acute appendicitis, an additional factor enters into the problem, and that is the risk of spreading infection. It will be useful for our purpose to divide up the cases into three groups.

(1) *Those cases in which* the appendix is acutely inflamed, but as yet there is no indication of peritoneal involvement; from our point of view they correspond entirely to the chronic cases, and all that has been said will apply to them.

(2) Those cases in which there is localised abscess formation. It is in this group that the greatest difficulty arises in attempting to vindicate the claims of the rectus incision; *indeed*, if there were no diagnostic error and one could make quite sure that the abscess had reached the anterior peritoneum, then obviously the only logical incision is the McBurney. Unfortunately, the diagnostic error creeps in just as frequently here as in the chronic cases. During the past year I have seen several cases in which the abscess was by no means as localised as it appeared. In addition, it is only quite rarely that the pus has reached the anterior peritoneum at the time of operation, so that any incision which approaches from the front will be bound first to traverse the general peritoneal cavity and thus run the risk of spreading infection. Our ideas of the resisting powers of the peritoneum have luckily changed for the better; we now realise that the peritoneum is exceedingly resistant to infection provided it is not overwhelmed by massive doses. Most of such cases will be drained, and it is difficult to see that the risk can be any greater if the abscess be drained towards the mid-line than if it be drained directly outwards, considering that the general peritoneum will have to be traversed anyhow.

(3) The third group constitute those cases in which there is already general infection of the peritoneum present at the time of operation. In such cases there can be little doubt of the advantage of draining the whole cavity from a point as near the mid-line as possible rather than from an incision placed well out to the side. If it be thought advisable to drain the cæcal area in addition, this is easily done by passing a tube out from the incision.

Illustrative Cases.

Of the three groups of cases, therefore, it would seem that the advantages of the incision are only doubtful in those where the abscess is assumed to be completely localised, and it is because I believe that even in such cases this incision is often superior to the others, that the following cases are recorded with some detail, for they illustrate many of the points mentioned above in its favour.

(1) and (2) Two cases of appendicitis were admitted to Charing Cross Hospital together; the first was a girl of 19 years, and the second a man of 45. Their histories were *precisely similar both as regards duration and symptoms*, and in both cases what was apparently a well-localised abscess was felt. I decided as a test to use the McBurney incision in the first and the inner rectus incision in the other. The similarity of these cases was continued at the operation, indeed, it would have been difficult to find two cases more alike. In both there was a fairly well-localised abscess, but, in addition, a quantity of exudation in the general peritoneal cavity. The appendices were removed and large cigarette drains inserted. The man's recovery was uninterrupted; he left hospital at the end of the third week. The girl, on the other hand, developed a number of residual abscesses, in the peritoneum on right and left sides; she was subjected to several further operations for the drainage of these, and eventually left hospital for a convalescent home, scarcely able to walk unaided, and having barely escaped with her life, at the end of three and a half months. I am strongly of opinion that had this case been drained through a more central incision there would have been no residual infection in the peritoneum, and her recovery would have been as rapid as that of her contemporary. Were this case an isolated one it would prove nothing, the individual differences of resistance being too great; unfortunately, however, such cases can be multiplied.

Of a fairly large number of instances only two more need be given to prove that they are not very uncommon.

(3) A child, aged 5, was admitted to the Queen's Hospital for Children suffering from an obvious appendicitis calling for immediate operation. The resident officer who performed the operation felt so sure of the localisation of the abscess that, contrary to the usual custom, it was decided to use the McBurney incision, through which a large drainage-tube was inserted. After a few days this child died; at the post-mortem examination it was discovered that the abscess was not so localised as had been thought, and that a large extension to the left had been very inefficiently drained by the tube passing in on the right side, although such an extension must almost certainly have been well drained by a tube passing through a rectus incision.

(4) The fourth and last case also occurred at the Children's Hospital. This case had already been diagnosed as an appendix abscess, and upon examination I could find no signs of general peritoneal involvement. So well localised did the abscess appear that McBurney's seemed the only logical incision to use. In view of the above considerations, however, I adopted the inner rectus incision. The actual abscess about the appendix was certainly very localised, but in addition there was a peritoneal infection extending well to the left and not localised. The actual appendix abscess was opened, the appendix removed, and a large tube inserted down into the pelvis, a smaller one being carried out to the right iliac fossa. The boy made a rapid recovery. It is very difficult to see how efficient drainage of both sites of infection could be obtained by any other than a fairly mesial incision.

The mere record of cases grows tedious, especially as everyone must have had numerous examples of the same type in his own experience. They prove, however, that this incision is not devoid of merit, and although to use it as a routine would lead one into the very error of stereotyping which one is trying to avoid, yet I believe that if the indications of these cases are carefully observed, it will be used more frequently than either of the classical incisions.

Summary.

(1) Excessive stereotyping of classical operations is undesirable in view of the variation in cases.

(2) The incisions of McBurney and Battle, while excellent in their way, both limit the general exploration of the abdomen.

(3) The diagnostic error in the case of appendicitis is considerable, and should be corrected if possible at the time of operation.

(4) By the inner rectus incision with the rectus retracted out the whole of the abdomen can be easily explored, while at the same time the accessibility of the right iliac fossa is not seriously affected.

(5) This incision is indicated in all cases except those in which the localisation of an abscess can be guaranteed.

(6) The scar following is a strong one, and no cases of secondary hernia have been recorded.

THE OPERATIVE TREATMENT OF PROLAPSE (PROCIDENTIA) OF THE RECTUM IN ADULTS.[1]

BY J. P. LOCKHART-MUMMERY, F.R.C.S. ENG.,
SENIOR SURGEON, ST. MARK'S HOSPITAL FOR DISEASES OF THE RECTUM, ETC.

PROLAPSE of the rectum in adults, while not a dangerous complaint, is certainly one of the most distressing as regards discomfort that a surgeon is called upon to treat. In time it causes complete incontinence of the fæces, and to a large extent prevents the patient from getting about or attending to any form of business. It is notorious that results of treatment have often been very unsatisfactory; it is quite a common thing to find that a patient suffering from this complaint has had several unsuccessful operations performed for its relief.

Conditions Producing Prolapse.

In principle a prolapse is similar to a hernia and requires the same conditions for its cure. In a hernia the condition is produced, first, by the giving way of the muscular and fibrous supports at or near a weak spot in the wall of the abdominal cavity, and, secondly, by the stretching of some part of the contained viscera, which allows it to pass more or less through the opening so caused. These are also the conditions producing a prolapse of the rectum.

In order to cure a prolapse of the rectum it is first necessary to replace and anchor the prolapsed bowel, and then to restore the anal canal so that it is no longer a weak spot in the floor of the pelvis. Both results must be secured, for if one only is obtained recurrence of the condition is almost certain. The method I here describe was first published in THE LANCET during 1910[2]; my excuse for describing it again is that since then I have had a much more extended experience of the operation and its results, and am convinced that it is far superior to any of the other methods. It must be understood that the condition here referred to as prolapse does not include prolapsed piles, however bad, but true procidentia of the rectum, in which all the coats of the rectum are included in the portion which comes down. As a rule the prolapse varies in length from 2 to 8 inches. In old-standing cases the anus is patulous and the muscles badly stretched, while in some it may be almost impossible to elicit any contraction of the external sphincter on stimulation. If there is any appreciable weakening of the sphincter the integrity of the anus must be restored, and the prolapse dealt with at the same time, or a good result cannot be obtained. It is this factor which renders prolapse in the aged so difficult to cure: the muscular tone is gone and cannot be restored, and the surgeon can only hope to narrow the anal orifice.

Method of Operation.

A necessary preliminary to operation is to get the lower bowel thoroughly cleared out, several days being required to do this properly. The principle of the operation is to restore the bowel into its normal place in the hollow of the sacrum and hold it there by firm adhesions. In order to obtain these dense adhesions I make use of healing by granulation, and with this object in view the space posterior and lateral to the prolapsing portion of the rectum is packed with gauze and only allowed to fill up slowly so as to get the densest possible adhesions between the rectum and the sacrum.

The operation is performed as follows: The rectum is thoroughly cleaned out with ether soap and lysol solution, and finally with 75 per cent. spirit and picric acid, the skin of the perineum and buttock being similarly rendered aseptic; after the prolapse has been returned a piece of gauze is placed in the rectum to prevent leakage *during the operation*. A *transverse* incision is next made about 2½ inches long midway between the tip of the coccyx and the posterior margin of the anus. This is deepened until the connective tissue between the rectum and the sacrum is opened. With blunt dissection or with gloved fingers this space is opened as high up as possible and laterally till the rectum has been freed thoroughly at the back and sides. The whole of the space thus opened up is now lightly packed with sterilised vaseline gauze 2 inches wide, and made with a sewn edge, so that it will not fray and leave particles behind. A very considerable amount of gauze tape is used, but the object is to get this spread as flat as possible and not merely to fill the pelvis with it, and so block the rectum. As much as 40 yards of gauze have been employed in some cases. The end of the gauze is left protruding from the wound, and if (as is usually the case) more than one piece is used all the ends are firmly tied together at the finish.

---

[1] Being a paper read before the Subsection of Proctology of the Royal Society of Medicine.

[2] THE LANCET, 1910, i., 641.

The next thing is to restore the anus; the type of operation for this purpose will vary according to the condition to be dealt with. My usual method is to extend the ends of the previous incision forward on each side to about half-way between the anterior and posterior margins of the anal orifice. The flap thus formed is dissected up so as to expose the posterior half of the external sphincter. This muscle is then carefully defined and the lateral portions sewn together from behind forwards until the anal orifice is narrowed to the extent considered desirable. No. 1 catgut is used for the stitches, and they are not pulled tight enough to cut through the muscle fibres, but just to bring the sides of the sphincter in close contact. Supporting sutures are put in, and then the flap is loosely stitched back in position, leaving room for the removal of the gauze packing later. A short tube is placed in the rectum to prevent prolapse should the patient strain coming round from the anæsthetic, and the whole perineum covered with sterilised dressings.

Treatment after Operation.

The wound is dressed twice daily and fresh dressings applied, but the packing is not removed for a week. At the end of this time an anæsthetic is given, all the packing removed, and a fresh lot of gauze introduced; this, again, is left in for five days or a week, and then removed; this time no fresh gauze is introduced, a drainage-tube being placed in the cavity left by its removal. The wound should not be allowed to heal under three weeks; in fact, the more slowly it heals the better the result. The bowels are kept confined until the seventh day after operation, when they are relieved by an enema before the removal of the packing; after this they are opened daily with an enema, a slipper bedpan being used. The patient is not allowed out of bed for six weeks and not allowed to sit up for an action of the bowels for two months at least. It is most important in view of the large area of cellular tissue opened up that there should be no sepsis at the time of the operation, but sepsis later is almost certain to occur after the removal of the packing, and is, in fact, desirable. The slower the wound heals and the more fibrous tissue involved the better the result.

Results.

I think I may say that the results of the operation are very good. The earliest case was treated as long ago as 1908, so there has been plenty of time to test the question of a permanent cure. Out of the total of 32 cases there have been only five failures. Two of these were permanently cured by repeating the operation. In one other case two operations failed to cure the patient, but in that case there were special circumstances; the patient, a lady aged 52, suffered from a chronic nervous affection of the spinal cord, which caused great difficulty in micturition, and consequent straining was the cause of recurrence of the prolapse. She was also mentally deficient, so that it was difficult to get her to take reasonable care of herself. With these exceptions all the cases were cured. In quite a number of cases several previous operations had been performed unsuccessfully by other methods. As regards risk, this would with proper precaution appear to be negligible. So far I have not met with any serious complication.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

DISSEMINATED SCLEROSIS TREATED WITH INTRAVENOUS ARSENIC.

BY J. R. PERDRAU, M.B., B.S. LOND.,
PATHOLOGIST, LAMBETH INFIRMARY;
AND
G. F. STEBBING, M.B., B.S. LOND.,
SENIOR ASSISTANT MEDICAL OFFICER, LAMBETH INFIRMARY.

IN view of the work that has been done in recent years tending to show that disseminated sclerosis is of spirochætal origin the following notes are of interest, showing the effects produced in a case of disseminated sclerosis which was treated by intravenous injections of arsenic:—

J. M. F., aged 26, married, was admitted to the infirmary April 24th, 1916. She had had no previous illness and had three children, all alive and well at the time of her admission. Six months before admission she had noticed loss of power and sensation in the left hand, which had only lasted a short time. Five months later similar symptoms appeared in the right hand and she began to drag her right foot. She became gradually worse and was bedridden for a short time before her admission.

On admission she was well nourished, and there were no physical signs of disease in the heart, lungs, or abdomen. The grip of each hand was very weak; the deep reflexes were present, equal, and active; there was no loss of sensation to light touch, pain, or heat, but there was considerable ataxia of the arms, and she was unable to appreciate weights correctly. The legs were paralysed and flaccid, the deep reflexes much exaggerated, and the plantar reflexes extensor; sensation to light touch, pain, and heat was normal, but the patient complained of pains in her legs at night. The sphincters of the bladder and bowel were affected. There were no lesions of the cranial nerves; the pupils reacted to light and accommodation; the sight, speech, and mental condition were normal. Patient had slight scoliosis; there were no pains in the spine and no "root pains."

A diagnosis of a lesion of the pyramidal and posterior columns—i.e., combined sclerosis—was made. The Wassermann reaction of the patient's blood serum was returned "positive." There was no clinical evidence of syphilis in the patient or her husband, and repeated examinations of the latter's blood were always "negative." However, on the strength of the positive Wassermann, the patient was given a course of intravenous arsenic in the form of galyl in concentrated solution, followed by weekly intramuscular injections of metallic mercury. The improvement in the patient's condition was immediate. She was soon able to move her legs in bed, she recovered control of her sphincters, and four and a half months later she was able to walk about and go home. She attended the infirmary regularly for antisyphilitic treatment, and the Wassermann reaction which was tested every three months, was always negative. A mild paresis of the legs remained and never completely cleared up, but the patient, from being completely bedridden, had become able to walk about, to walk to the infirmary, and to do her housework, and in view of this dramatic improvement, which had apparently been effected by the treatment, the case was looked upon as one of syphilitic meningo-myelitis.

On April 8th, 1918, the patient was readmitted for a severe relapse.

On admission there was definite spastic paraplegia and occasional incontinence. The pupils reacted normally and sight and speech were not affected. Intramuscular injections of mercury were resumed, combined with treatment by massage and radiant heat. Only a slight improvement occurred, and the patient took her discharge on May 8th, 1918, her mental condition beginning to show a little deterioration—e.g., she became discontented and complained without sufficient cause, &c.

She was not seen again until Oct. 8th, 1919, when she was readmitted in a much worse condition than she had been in at any previous time. She was emaciated, bedridden, and suffering from a large bedsore over the sacrum. She was completely paralysed in both legs and incontinent of urine and *fæces*, but had no disorder of sensation; her pupils and sight were normal, and remained so to the end. But a new order of symptoms had appeared; her speech was slurring and characteristic of the kind observed in G.P.I. Her mental condition was still more typical of that disease; *she was disorientated for time and place, was inordinately happy* considering her condition, very emotional at times, and had many delusions of grandeur—e.g., she was a princess, possessed vast sums of money, and kept giving orders for goods on an extravagant scale, &c. The Wassermann reaction of her blood serum remained negative. She got gradually worse and died on March 27th, 1920.

Remarks.

Up to the time of this patient's death, in spite of the absence of pupillary signs, the case was considered to be an unusual one of syphilis of the central nervous system, beginning as a meningo-myelitis, passing into a stage where the physical signs were referable to a healing pachymeningitis and ending as a case of parenchymatous syphilis of the brain (G.P.I.). The post-mortem examination, however, upset the whole of the clinical observations and deductions. The central nervous system presented the typical lesions of disseminated sclerosis with the characteristic haphazard distribution of soft pink patches of sclerosis in the spinal cord and medulla and in the white matter of the brain. The microscopical findings confirmed the naked-eye appearances. No pachymeningitis was found, but there was a mild leptomeningitis.

This case is of interest for the following reasons: (1) The simulation, at first, of a spinal syphilitic lesion, and, later on, of syphilis of the brain by a case of disseminated sclerosis. (2) The remarkable improvement which occurred in a bedridden case of disseminated sclerosis. The improvement was so great that the patient, after having been completely paralysed in both legs, was able to walk without help for two years before a relapse occurred. (3) The possibility that intravenous injections of arsenic may have played some part in producing this improvement.

A NOTE ON THE

ADMINISTRATION OF BILE SALTS IN INFANTILE MARASMUS.

BY E. F. KERBY, M.B., B.S. LOND.,

LATE HOUSE PHYSICIAN TO THE EVELINA HOSPITAL FOR CHILDREN, LONDON.

THE following report is based on observations carried out at the Evelina Hospital in 1918 on four marasmic infants. Publication of results has been delayed until now on account of the limited number of cases hitherto investigated and the paucity of laboratory evidence corroborating clinical observations. However, Dr. R. Miller's recent article, "Cœliac Infantilism: Its Fat Digestion and Treatment by Bile Salts,"[1] and Dr. R. Armstrong's letter[2] have encouraged the present publication, especially as the literature is peculiarly deficient in papers dealing with the clinical aspect of bile-salt therapeutics. On the other hand, there are a number of very interesting pathological investigations that have a bearing on the rationale underlying the treatment to be described. For reference to the researches of W. Jacubowitsch,[3] A. Baginsky,[4] and Arvo Ylppö[5] I am indebted to Dr. W. M. Feldman. Papers by H. Roger,[6] H. Dubin,[7] and R. Simonini[8] were also consulted, though all these investigations had been undertaken with different aims in view.

While it appears unprofitable at this juncture to discuss the particular theories involved, it may be stated that increased fat assimilation is thought to be only one of several therapeutic effects of bile salts. It is further suggested that cases of marasmus most likely to respond to the treatment are those following acute intestinal infections and chronic disorders of the type of H. Finkelstein's "balance disturbance," described by H. C. Cameron as "cow's milk atrophy."[9]

All patients reported in the present series belong to the large group of infants showing evidence of marasmus without other physical signs. In Case 2 the presence of congenital syphilis was suspected, but could not be established. Cases 1 and 3 had a history of wasting of long duration, which in the latter case followed on an attack of infective enteritis. In no case was there any evidence of cœliac disease or any macroscopic indication of fat excess in the fæces. While normal as a rule, the stools were occasionally bile-stained and unduly frequent.

The average dose administered in the course of this investigation consisted of gr. ¼ of the mixed sodium glycocholate and taurocholate for infants 3 months old. No attempt was made to investigate the differential action of the two acids. The patients' diet was kept as uniform as possible; it consisted of pasteurised cow's milk suitably diluted.

CASE 1.—A. B., a girl, aged 10 weeks, admitted July 4th, 1918, weight 3·2 kg. During the first month weight dropped to 2·9 kg., but rose again to a maximum of 3·39 kg. on August 16th. During following month she lost again steadily. On Sept. 19th, her weight then being 3·06 kg., bile salts were administered. She immediately began to put on weight; except for a slight set-back caused by enforced substitution of condensed for fresh milk, this improvement continued throughout her stay in hospital. A fortnight after the administration of bile salts had been stopped her weight had reached 4·12 kg. Therefore, after the first period of 10 weeks in hospital she had lost 0·14 kg.; during the second 10 weeks, while bile salts were given, she gained 1 kg. Her parents reported at the beginning of May, 1919—that is, six months after discharge—that they "could almost see her put on weight" and that she was fit in every respect.

CASE 2.—C. D., a boy, aged 2 weeks on admission; emaciated and very weak. Frequent attacks of vomiting and diarrhœa. Though he was not thought to suffer from typical marasmus, bile salts were administered for two short periods without arresting the steady drop in weight. Altogether he had lost 0·5 kg. when he died. One Wassermann examination had been returned negative, but suspicions of the presence of syphilis remained.

CASE 3.—E. F., a girl, aged 8 weeks, admitted for infective enteritis. A normal infant before this illness, she became marasmic after the attack of enteritis had subsided. On admission her weight was 2·8 kg. After a temporary rise to 3·06 kg. it dropped to 2·7 kg. After 10½ weeks it was just 3 kg. She was then given bile salts. With but one interruption, during an attack of otitis media with otorrhœa, her weight steadily increased to 3·8 kg. During the first 10½ weeks in the ward she had gained 0·2 kg., after many oscillations; during the second period, lasting 6½ weeks, while bile salts were administered, she gained 0·8 kg.

CASE 4.—G. H., a boy, aged 7 weeks. Bile salts were given for one short period only, but neither this nor any other treatment led to a marked improvement. His condition was practically the same on discharge. This case is included merely for the sake of completeness.

Conclusion.

Cases 2 and 4 cannot be shown to have derived any benefit from bile salts. It may be argued that Case 2 was syphilitic, or, in any case, was too much handicapped by infective enteritis to recover with any form of treatment. In judging the improvement in Cases 1 and 3, two outstanding features must be considered in addition to the increase in weight. In the first place neither patient showed any improvement during the first ten weeks in hospital. In spite of all efforts to find a suitable treatment the downhill course had not been stayed. Secondly, the steady general improvement synchronous with the bile-salt treatment impressed all clinical observers. The infants, apathetic and feeble, and to all appearances moribund, responded from the very outset of treatment until they were vigorous and thriving like normal babies. It must be emphasised, therefore, that the actual gain was greater and more complex than a mere increase in weight.

In conclusion, I wish to express my gratitude to Dr. D. Forsyth and Dr. E. P. Poulton for facilities of study and permission to publish these notes.

A SPECIAL meeting of members of the medical profession interested in the subject of the advance of medical education in China will be held on Monday, Feb. 21st, at 5.30 P.M., in the Barnes Hall, Royal Society of Medicine, 1, Wimpole-street, London, W.

BRITISH HOSPITALS' ASSOCIATION.—A conference, called at the request of the British Hospitals Association, was held at the Royal Portsmouth Hospital on Jan. 27th. It was unanimously decided to form a regional committee of representatives of hospitals in Hampshire, Isle of Wight, and part of Sussex, in order to guard the interests of voluntary hospitals, and to give to the Central Committee a combined opinion on questions affecting them. Each hospital will be asked to nominate two delegates. Meetings will be held quarterly in various towns in the district.

Medical Societies.

MEDICAL SOCIETY OF LONDON.

A MEETING of this society was held on Jan. 24th, Sir WILLIAM HALE-WHITE, the President, being in the chair, when Dr. A. FEILING read a paper on

Multiple Neuritis.

He said that the term "neuritis" was somewhat misleading, since it conveyed the idea of an inflammatory lesion, rather than of a degeneration of the parenchyma of the nerves. Modern researches had all tended to confirm the view held by the older observers and to enlarge our conception of the disease as one where the neuritis was only part of a generalised disease process which might affect other organs even primarily, and the nerves and central nervous system secondarily. The essential cause of the disease might, broadly speaking, be described as some poison which was either introduced from without (for example, the chemical poisons of alcohol, lead, or arsenic) or elaborated in the body by the growth of bacteria such as the diphtheria bacillus, or which was part of a general infection or intoxication, such as occurred in the specific infections, typhoid fever or influenza, for example. Multiple neuritis might also occur in conditions of altered metabolism, such as were found in diabetes, in cachectic conditions such as tuberculosis or cancer, or in states where a dietetic insufficiency played a large part, as in beri-beri. Pathologically, the process was essentially one of degeneration, and though inflammatory changes were present in some forms they were an inconspicuous feature. Recently more attention had been focused on the changes found in the central nervous system, and more exact methods had brought these changes into increasing prominence. Thus, Marie warned us that the disease was not limited to the peripheral nerves, but that changes might be found in the spinal cord and medulla in many cases. The ganglion cells in the anterior horns constantly showed the changes of chromatolysis, while the posterior root ganglia were often affected. Which was the primary condition had long been a moot point, but the most acceptable explanation was that the action of the toxin fell on both, so that the whole motor neurone, and in many cases the sensory neurone as well, was attacked. The recent researches of Orr and Rows on lymphogenous infection of the central nervous system had demonstrated ascending lymph streams in the spaces of the perineural sheaths, and that toxins could reach both the spinal cord and medulla by this route. F. M. R. Walshe had applied this conception to explain the pathogenesis of diphtheritic paralysis, and had pointed out that the varying nature of the paralysis might be explained by the seat of the toxin in the body. Thus in the ordinary case of faucial diphtheria toxins were elaborated in the membrane and passed to the medulla or mid-brain by the perineural lymph channels of the cranial nerves, and hence the early involvement of those nerves by the action of the toxins on their centres. The multiple neuritis—i.e., that of the arm and legs—was referred to a blood-borne general toxæmia which was usually of later date than the cranial nerve involvement. This contention received support from his experience of diphtheria in the Egyptian Expeditionary Force, in which the site of the infection was the skin in many cases, and in which there was a close connexion between the situation of the primary lesion and that of the initial paralysis. *The importance of a* generalised infection of the central nervous system was also evidenced by the pathology of acute febrile polyneuritis. Such far-reaching changes as involvement of the grey matter, muscular degeneration, and hepatic inflammation could be demonstrated. Bradford, Bashford, and Wilson regarded the disease as essentially a septicæmia, the central nervous system being affected by way of the nerve trunks.

Having spoken briefly of the general signs and symptoms of multiple neuritis he referred more particularly to the work of Walshe on diphtheritic neuritis, and that of Gordon Holmes, and J. R. Bradford, E. F. Bashford, and J. A. Wilson on acute infective polyneuritis.[1] The former had forced us to realise the importance of the skin as a possible portal of entry of infection in multiple neuritis, and impressed upon us the general involvement of all the elements of the nervous system. Bradford, Bashford, and Wilson had concluded as follows:—

1. *So-called acute febrile polyneuritis is a very definite* entity, capable of being separated clinically from other diseases of the nervous system.
2. It is a diffuse affection of the nervous system affecting the spinal cord, spinal ganglia, and peripheral nerves, with but a slight incidence on the cerebral cortex.
3. The lesion is essentially one of the nerve elements—cells and fibres.
4. The malady can be transmitted experimentally to the monkey, and the characteristic lesions reproduced in the experimental animal.
5. A living virus can be shown to be present both in the human cases and in the inoculated monkeys.
6. The disease can be reproduced in the monkey by the suitable inoculation of the virus in pure culture, and the virus can be recovered from the experimental animal.

Similar cases had been noted in civil practice, and he recounted two from his own experience. He then spoke of multiple neuritis following influenza, many cases of which he had met with during the last epidemic. The symptoms were chiefly on the motor side. Wrist-drop and foot-drop were both fairly common, while less frequently the paralysis had involved the muscles of the trunk. He had seen paralysis of the abdominal muscles and of the diaphragm. Patrick had analysed the occurrence of facial paralysis in multiple neuritis, and had found that it occurred most commonly in influenzal cases. Multiple neuritis in the typhoid fevers was very uncommon, and he had never seen a case of any severity. He had met with one remarkable case following typhus in which the muscles most affected were those of the *shoulder girdle. Dysentery, particularly the bacillary* type, could undoubtedly be responsible for multiple neuritis. Several examples which had come under his observation were all mild, and exhibited no special feature beyond a slight motor paresis and subjective disorders of sensation with loss of the knee- and ankle-jerks. After laying stress on the importance of regarding all cases of multiple neuritis as examples of infection or of intoxication affecting the whole body and not merely confining attention to the nervous system, he remarked upon the apparent diminished frequency of alcoholic neuritis, and asked the views of the meeting on the occurrence of multiple neuritis in rheumatoid and other types of infective arthritis.

Discussion.

The PRESIDENT said that he was in full agreement as to the implication of the rest of the nervous system. It was difficult to understand why particular nerves were damaged by particular poisons—for example, the musculo-spiral by lead and the anterior tibial by arsenic. Was there some subtle chemical difference between the two nerves? Another example was the confinement of multiple neuritis of diphtheria in many cases to the mouth and its neighbourhood. He had twice seen neuritis due to alcohol fatal from involvement of the vagus. To ascribe the selection of particular nerves to "selective affinity," as was so often done, was no real explanation. He thought there was certainly a decrease in alcoholic neuritis, and recognised little association between neuritis and rheumatoid arthritis.

Sir DAVID FERRIER, while agreeing that the centres were affected, said there was no doubt that the brunt fell on the peripheral nerves, and until recently pathologists had been unable to discover the lesions of the central nervous system. Paralysis of peripheral neuritis differed from that due to affection of the anterior horn in that it showed itself more particularly in the extensor muscles. This was seen in the case of alcohol, lead, arsenic, and almost every form. If a nerve were pressed upon, the first muscles to become paralysed were again the dorsi-flexors. In pressure on the recurrent laryngeal nerve this was true of the abductors. It appeared that the extensors and the abductors were more vulnerable, and clinically this afforded an important distinction between neuritis and poliomyelitis. The grouping was different from poliomyelitis, and the paralysis corresponded with function. During recovery, again, the last muscles to recover were the extensors.

Handprints of Mental Defectives.

Dr. F. G. CROOKSHANK read a paper on Handprints of Mental Defectives, with special reference to those of Mongolian imbeciles. In order to make clear the point to which he desired to draw attention he explained the lines on the normal palm, using for convenience, without prejudice, the terminology of the palmists. Three main lines were seen on a normal well-developed palm. The first, which skirted the ball of the thumb and was known as the "line of life" being correlated with a well-developed thenar eminence, was more marked in those who are vigorous, both bodily and mentally. Of the two other principal lines one, called the "line of heart," took origin from between the pads at the bases of the first and second fingers and ran outwards to the ulnar border; the other, nearer the wrist, rose near the hypothenar eminence and ran outwards to the cleft between the thumb and the base of the index finger. Though these primary lines were correlated with function they were not actually, and for each individual, developed during and by the use of the hand, as were most of the secondary and tertiary lines. They were normally present in the last week or weeks of fœtal life, their presence at this early stage being an example of the operation of what is called the law of anticipation; that is to say, characters acquired for the race by response to need tended to appear in succeeding generations at early stages of development in anticipation of exercise of that function with which they were correlated and for which or to which they were adapted. When an ill-brought-up child, an idiot, or an ape grasped a fork, a stick, or a straw, not as we hold a pen or a knife, but across the palm, a broad transverse crease was made which showed how the lines of head and heart had been differentiated from one transverse primitive line suited to this primitive usage of the hand. Such a line was seen on the hands of many monkeys, as in the rhesus, and of some apes, especially the orang, and it was this single transverse line that was seen on the palm or palms of many Mongols. In Beamish's "Psychonomy of the Hand" (1864) there was a representation of this type of marking as seen in the hand of a congenital idiot in Cork County Asylum, and some years ago he had seen a similar print from the hand of an American doctor executed at Chicago for murder. Otherwise he believed that this morphological peculiarity had escaped observation. Professor F. Wood Jones, however, mentioned it, though not in connexion with Mongolism. There was a general resemblance between the prints of the right and left hands of a young normal in respect of the primary lines, but amongst Mongolian imbeciles there was often, even at an early age, a difference between the right and left palm. As a rule, the left was the more primitive, but when both were primitive the child was usually of a low grade.

It was, however, not only in respect of Mongolism that a study of hand prints was interesting. Certain mental defectives and some nervous children who were not cretins, but who responded to thyroid treatment, displayed a very characteristic hand print. There were coarse deeply-scored intersecting lines giving the appearance of a photograph from an aeroplane of a barbed wire entanglement. This type was sometimes met with conjoined with that of Mongolism. A good deal of evidence had lately accumulated to show that in Mongolism there was an element of dysthyroidism. The occurrence of mixed types was not so uncommon as was thought, and children with a mild degree of Mongolism, but who were not imbeciles, often became myxœdematous in later life. Besides these two chief types there was another of considerable interest. In the peculiar hands of patients suffering from dementia præcox the lines running up divergently from the wrist were very marked, as in the chimpanzee, and the same thing was seen in the hands of children of the physical and mental type that stamped them as candidates for dementia præcox. Though it was easy to recognise the three types of hand prints, nevertheless mixed cases occurred. The Mongolian line, as seen in adults who are called normal (but who, though able, are usually anything but commonplace), was not a sign of imbecility, but indicated the unit one might call Mongolian, albeit not dominant but in recession. He showed a large number of hand prints to illustrate his paper.

Dr. R. L. LANGDON-DOWN said that particular hand prints were only true, broadly speaking, of those imbeciles called Mongols. The special mal-development of the lines which had been described was confined to Mongols, and though in others there might be irregularity they were not of the same type. They were not seen in all imbeciles. He agreed that in some cases in which there were none of the ordinary traits of Mongols the lines might be useful in diagnosis. He associated both the Buddha posture and the grooves in the hands with the abnormal flexibility of joints and harshness of the skin. Another feature was shortness of the index fingers.

ROYAL SOCIETY OF MEDICINE.

SECTION OF MEDICINE.

A MEETING of this section of the Royal Society of Medicine was held on Jan. 25th, Dr. A. F. VOELCKER, the President, being in the chair.

Dr. P. J. CAMMIDGE read a paper on

Observations Bearing on the Ætiological Classification of Diabetes Mellitus.

After briefly summarising a series of experiments on the changes in the blood and urine associated with pancreatic disease, published in THE LANCET[1] in conjunction with Mr. Cairns Forsyth and Mr. H. A. H. Howard, in which it was shown that the "difference value" of the blood and the iodine coefficient of the urine, estimated at hourly intervals before and after a test-meal taken fasting, vary inversely as the percentage of sugar in the blood and the output of sugar in the urine respectively, the speaker proceeded to describe the results of the application of similar methods to the study of diabetes mellitus. It had been found that in a series of 100 consecutive cases 33 gave curves corresponding to one or other of those obtained with partially or totally depancreatised dogs, and it was inferred that the diabetes was probably of purely pancreatic origin in about this proportion. The remaining cases were divisible into three groups according to the relation between the difference value and blood-sugar curves. In one the difference value starting at or about zero in the fasting state rose with the percentage of sugar in the blood after a meal and continued to rise as the blood sugar dropped again after reaching its maximum. Experimental and clinical evidence was brought forward which indicated that in this type of case the functions of the liver were being imperfectly carried out, and it was concluded that this, the "hepatic" type of curve, probably indicated a different form of diabetes from those in which a "pancreatic" curve was found. In another group the difference value of the blood was found to be abnormally high in the fasting condition, as in "pancreatic" cases, but instead of the ingestion of food being followed by a fall a rise occurred, as in the "hepatic" type. It was, consequently, suggested that cases showing curves of this character were suffering from a combined pancreatic and hepatic disorder. In the remaining cases the difference value and blood-sugar curves ran concurrently, a rise in the one being associated with an increase in the other and vice versa; moreover, in most of them the peak of the blood-sugar curve after a test-meal had been found to occur at the first or second hour instead of at the third hour, as in a normal individual. No definite opinion as to the pathology of this group was expressed, but, as it included cases of exophthalmic goitre and acromegaly, it was suggested that curves of this description might be an expression of disturbances in the nervous system or in the ductless glands, apart from the pancreas. The subject is at present being investigated experimentally. So far as a limited experience allowed of inferences being drawn, the pancreo-hepatic type was much the most serious as regards prognosis, the pure pancreatic type came next, the true hepatic condition was comparatively innocuous, while no deaths had so far occurred among the patients giving a concurrent type of curve. Dr. Cammidge said that the paper was a preliminary communication, and that modifications might become necessary as the investigation advanced.

---

[1] THE LANCET, August 21st, 1920, p. 393.

Dr. E. P. POULTON'S paper on the treatment of peptic ulcer by means of gastric and gastro-duodenal tubes appears in full in the present issue of THE LANCET.

SECTION OF OTOLOGY.

AN ordinary meeting of this section of the Royal Society of Medicine was held on Jan. 21st, Mr. ARTHUR CHEATLE, Vice-President of the section, occupying the chair.

CAVERNOUS SINUS THROMBOSIS.

Mr. T. RITCHIE RODGER (Hull) read a paper on four fatal cases of this condition which had been under his care. The origin of the trouble was different in each case. In the first patient the superior petrosal sinus had been primarily infected from the middle ear or the internal ear without previous involvement of the sigmoid or the lateral sinus. The second case had a more usual origin—namely, a carbuncle on the nose. The third was of the middle-ear type, in which the sigmoid was thrombosed, the process extending to the cavernous sinus, presumably viâ either or both petrosals. The fourth was an example of infection following a frontal sinusitis. This was the only case of the four in which permission could be obtained for a post-mortem examination. In this a purulent exudate was found covering the whole of the left side of the brain, and several ounces of pus drained into the basin. The lateral, sigmoid, and longitudinal sinuses were normal. The circular sinus and the anterior part of the right cavernous sinus showed pus and soft thrombi. The dura was adherent to the roof of the left frontal sinus, and the bone was dark-coloured. Removal of this dark bone revealed a frontal sinus full of thick pus and gangrenous mucous membrane. A similar condition was present in the left antrum of Highmore and in the ethmoid cells. Mr. Rodger discussed the methods of approach to the sinuses and the possibility of saving these very fatal cases by setting up a suction action by lavage of the jugular bulb, the idea being to aspirate the septic clot from the inferior petrosal sinus. He said that although cavernous sinus thrombosis was one of the most fatal conditions met with, a sufficient number of recoveries without direct attack had been recorded to encourage otologists to use every available means to attain that end. When dealing with sigmoid sinus thrombosis the most scrupulous cleansing of the mastoid cavity must be carried out before opening the vein, and the greatest care observed in inserting the upper plug. Also vaccines and every possible aid to increase the patient's resistance should be employed, and one of the most important of these means he considered to be fresh air.

Mr. W. STUART-LOW expressed his decided preference for the cortical mastoid operation over the radical operation for young patients. These patients showed great powers of recovery, and after the radical operation there was a considerable tendency for the sepsis to extend into the veins. He also laid stress on an efficient preparation of the field of operation before attempting treatment, and the use of a cage over the wound instead of a tight bandage, to allow of free access of air.

Mr. CHEATLE considered that cases of the kind, when once established, were hopeless. He referred to the operation on the cavernous sinus which was designed by Sir Charles Ballance, and described before the Otological Congress at Boston, U.S.A. He, the speaker, referred to the case of a child which he recently had. The patient was at once operated upon, but all that was found was pus in the antrum. Signs of cavernous sinus thrombosis developed and death ensued. At the autopsy, sepsis was found to have extended to the superior petrosal sinus, which was evidently the pathway of the infection to the cavernous sinus. He referred to the danger of syringing the sinus in operations for thrombosis of the lateral sinus.

Dr. A. A. GRAY (Glasgow) said he had seen four cases of recovery from the condition under discussion, but they may not have been septic cases.

Mr. HAROLD KISCH spoke of recovery in a case of cavernous sinus thrombosis which was under his care. It was that of a Punjab Mahomedan who was wounded in the scalp in 1917. When seen, the scalp was œdematous and very septic. Several incisions were made, and the veins of the scalp were full of pus. He had a high temperature, pain, proptosis, chemosis, &c.; but in a few days there was complete recovery. Native Indians often showed remarkable powers of dealing with sepsis. This man was nursed in a tent, which might have been a factor in his recovery.

Mr. RODGER replied.

EXHIBITION OF CASES.

Tinnitus with Large Rhinolith.

Mr. L. COLLEDGE showed a woman, aged 59, who had been complaining of tinnitus in the right ear for many years. There had also been some discharge from the right nostril, with obstruction of it, causing, however, very little pain, and there was no deafness. There was suppuration in the right antrum of the nose, and some small mucous polypi were present. The stone was felt with the probe, and was removed by an operation on the right antrum; the rhinolith had to be partly crushed before removal to avoid damaging the nose in extraction. A carious second bicuspid tooth was also removed, and there had been great relief since.

Pyorrhœa Alveolaris Affecting the Ears.

Mr. A. J. HUTCHISON showed two cases illustrating this relationship. The first, a girl aged 18, complained of increasing deafness and tinnitus in both ears, but the membranes appeared normal. Following the discovery of pyorrhœa five teeth were extracted; the tinnitus ceased, and hearing greatly improved. The second, a man, had ear pain, which started after bathing, and for 13 months had a varying discharge, and later had pain in knee, elbow, and neck. Pyorrhœa was discovered, teeth extracted, and within two weeks the ear became dry, hearing improved, and the joint-pains ceased.

Long Retention of Bullet in Ear.

Mr. KISCH showed a private soldier who, in January, 1916, was admitted to a military hospital with extreme rheumatoid arthritis in many joints, and emaciation. There was a profuse offensive discharge from the left ear, and the middle ear was filled with granulations; the mastoid was tender, and there was a tendency to spontaneous nystagmus. On exposing the middle ear the base of a rifle bullet could be seen just below the promontory, and it was extracted entire. There was no sign of fracture of the external auditory meatus. The ear progressively recovered, and his joints improved sufficiently for him to live an ordinary life. The bullet had been in situ 15 months.

Foreign Body in Mastoid Antrum.

Mr. T. JEFFERSON FAULDER showed a boy, 8 years of age, in whom a bead was found in the deeper part of the meatus, beyond the isthmus. It completely filled the lumen and was surrounded by a small rim of wax. Attempts at extraction by the natural route failed, and on making a post-aural incision the bead could not be found in the meatus or the tympanum. A later operation exposed the foreign body lying among granulations in the antrum. It appeared to have arrived there by way of a much enlarged aditus.

Deep Aneurysm Involving the Temporal Bone.

Mr. NORMAN PATTERSON showed a patient with this condition, and described the operation he proposed after ascertaining what set of vessels the aneurysm was connected with.

Among the other cases was one by Mr. G. J. JENKINS, Probable Epithelioma of Auricle; and by Mr. W. M. MOLLISON (1) Tympanic Exostoses, and (2) Meatal Polypus due to sinus of the superficial bony meatal wall.

HARVEIAN SOCIETY.

THE FUTURE OF THE POOR-LAW INFIRMARY.

A MEETING was held on Jan. 27th at the Paddington Town Hall, with Dr. G. DE BEC TURTLE, the President, in the chair, when the discussion on the Future of the Poor-law Infirmary,[1] adjourned from Dec. 16th, was resumed. A letter was read from Colonel F. E. Fremantle, M.P., regretting his unavoidable absence, and urging that the problems should be attacked on broad lines.. The opening addresses, by Dr. A. G. Stewart and Dr. R. Dudfield, appear in full in the front part of this issue of THE LANCET.

Dr. J. B. COOK (West Middlesex Poor-law Hospital) spoke of his 16 years' experience of the inside working of an infirmary. The criticisms made against the equipment and treatment of patients were quite unfounded, anyhow as regards modern infirmaries in or near London. Dr. Wilson had suggested that Poor-law infirmaries had no future; if they were as he described, they certainly were not deserving of one. Dr. Charles Buttar had described them as the rubbish-heap of practice. The speaker was proud to have such rubbish on his heap, and confirmed Dr. Stewart's remarks as to the proportion of acute cases treated, the adequate equipment, the facilities for consultation and for pathological investigation, and the excellence of the training of nurses in modern infirmaries. In his opinion the future of the Poor-law infirmaries was assured. They were supported by public funds and would become State hospitals, and therefore their absorption by voluntary hospitals was unlikely. The future of the voluntary hospitals was much more uncertain. The machinery of State hospitals was partly established in the fever and mental hospitals and the infirmaries. In the future the State was bound to extend its care of the sick, which was too important to be left to voluntary efforts. The personal interests of members of the staff of voluntary hospitals were secondary to those of the sick which were the chief concern of the State, but the staff would not necessarily suffer. Why should not medical men find in State hospitals the same opportunities for advancement and advertisement, and be paid instead of exploited? Arrangements for the instruction of students could easily be made. The four points Dr. Cook wished specially to emphasise were: (1) That infirmaries would become State hospitals, whereas the voluntary hospitals would exist only as long as their funds existed. The State must in time enlarge the State hospitals, subsidise voluntary ones, or do both. (2) The infirmaries should be given more resident medical officers. (3) Specialists should be available for consultation when required, and X rays, electric treatment, and pathological investigations should be possible. (4) Paying patients should be allowed; this would be a boon to thousands of patients of the middle classes.

Dr. R. H. COLE gave some historical data showing how much the Poor-law infirmaries have done for mental cases. There was now a movement towards the establishment of out-patient clinics at infirmaries for early mental cases. The practitioner at present found it difficult to deal with such cases. In Dr. Cole's opinion the infirmaries did very good work, but were still capable of vast improvement. The great difficulty was the question of money. He trusted that Dr. Addison's Bill would be reintroduced next session.

Mr. V. Z. COPE said that the good work done by certain infirmaries was undeniable, but there was great inequality and need for standardisation. He thought that the separation of the executive functions of the medical superintendent from the medical and surgical ones was desirable; one excellent surgeon had said he would willingly give up the clinical side of his work and administrate only. As to consultants, in one infirmary 12 consultants were available. Such an infirmary should be made the centre of post-graduate teaching for local practitioners.

Dr. ALEXANDER BLACKHALL-MORISON pointed out that the State Medical Service had not absorbed more than half the profession, and that there remained 12,000 at least who were endeavouring to reassert its freedom. Dr. Blackhall-Morison emphasised the political bearings of the present trend of affairs in medicine, which he deplored. He did not think that Poor-law infirmaries should be alienated from the purpose of their existence, the care of the necessitous poor who would always be with us.

Dr. H. W. BRUCE (Southwark Poor-law Hospital) said that a good medical staff meant a good hospital, and that the staffing was all-important if State hospitals were to succeed. The general practitioner must be brought into it. There were certain practical difficulties. For example, public hospitals must be run on economical lines—this was not so necessary in voluntary hospitals. The cheapest way of staffing was by a whole-time general practitioner as resident, but the part-time system had so many advantages that the economic aspect was overshadowed. Unfortunately, the part-time general practitioner would be wanted by his private cases and in hospital in the morning. Another difficulty lay in the selection between the general practitioners of the district. Again, the question of consultants was thorny. If the infirmaries were to remain localised the consulting staff would have to be drawn from that of the voluntary hospitals, but if they were made to serve a wider area—for example, if the metropolitan infirmaries were brought under the L.C.C., the medical staff would then be large enough to develop its own consultants from members of the service who specialised. As to the medical superintendent, his position as combined administrator, physician, and surgeon could not now be retained, and the scope of his duties must be narrowed, but his future as an administrator who would coördinate the work of the medical staff was not less important.

Dr. NATHAN RAW, M.P., said that the Minister of Health was responsible for the health service for the nation, and had to consider how best to render this complete and adequate. The Minister had shown great courage in framing the Bill recently rejected by the House of Lords, and it would doubtless be reintroduced. The relative merits of Poor-law infirmaries and voluntary hospitals were less important than the problem of how best to use the existing facilities in providing an efficient health service for the nation. Dr. Raw said that of the existing beds for the treatment of various disorders the Poor-law infirmaries provided 95,000 and the voluntary hospitals only 40,000, whereas approximately 290,000 are provided by the State. The 40,000 beds of the voluntary hospitals were totally inadequate to cope with the mass of illness in the country. Dr. Raw said that he hoped never to see a State medical service; the present proposition was the conversion of the Poor-law infirmaries into a municipal service. In 1897 a Liverpool infirmary with which he was connected had applied for the provision of an operating theatre. A special meeting of the Local Government Board had been called together to discuss this request, which involved an important matter of policy. It was then decided to outstep the law, to introduce modern equipment, and now some Poor-law infirmaries are as well-equipped as voluntary hospitals. The present position of chaos, in which two sets of hospitals were competing, must cease. There was no longer the same need for aid for the destitute poor as the pauper class was disappearing. The modern attitude of trade-unionists was to desire neither charity from voluntary hospitals nor relief from the Poor-law, not being paupers. The infirmaries, therefore, should, in Dr. Raw's opinion, be taken over by local authorities and be used by members of the community. At present no one could be admitted unless sent by the relieving officer, except in cases of urgency. Until the law was altered it was surely unwise of infirmaries to open their doors to non-urgent paying patients, as this was not legal. The remedy was obviously to legalise this procedure by transferring to local authorities. We all admired voluntary hospitals, but the public will no longer contribute now that so much is taken from them for the support of the 290,000 beds in State-aided hospitals. The principle of transference of Poor-law infirmaries to local authorities must be admitted. They would then be open to all citizens, who would pay according to their means, and would be admitted free if they could not pay.

---

[1] See THE LANCET, 1920, ii., 1307.

Dr. J. C. MUIR (Whipps Cross Poor-law Hospital) considered it almost inevitable that hospitals should be supported more and more out of public funds. The difference between voluntary hospitals and the new hospitals would be that in the former teaching and research would be concerned with the advances of medicine, and at the latter the new knowledge gained would be put into practice.

Dr. C. L. TRAYLEN was glad to hear of an improved outlook for the general practitioner. It was encouraging to think that in the future they would be able to go into a hospital and see their cases through, as was now possible in the Willesden Cottage Hospital.

Dr. A. WITHERS GREEN said that disease was as much the business of the State as was the mud in the street. The insurance principle should be extended, and panel and Poor-law patients should be treated together in out-patient departments. There should be no payments made in infirmaries, but voluntary hospitals should charge fees. Dr. Green approved of the Gloucestershire scheme. He considered that general practitioners could not usefully be employed except to deal with out-patients.

Mr. HUBERT C. PHILLIPS said that great advances had been made in the infirmaries within the last 30 years. He thought the difficulty of selecting general practitioners for the staffs had been exaggerated. These appointments could be advertised and selections made from candidates by the medical superintendent in collaboration with a committee.

The PRESIDENT said that the same system could not be applied throughout the country; details must be left to the several districts. The linking up of voluntary hospitals with infirmaries was desirable; in some cases it might be convenient to affiliate two infirmaries to one voluntary hospital. As to the staffing, in Manchester the arrangement was that the junior staff of voluntary hospitals were attached to the infirmaries, and as they moved up their successors were automatically so appointed. There should be a combined medical committee of the staff of the voluntary hospital and of the infirmary attached thereto.

TUBERCULOSIS SOCIETY.

A CLINICAL meeting of this society was held at the Margaret-street Dispensary, London, W., on Jan. 24th, Dr. NATHAN RAW, M.P., the President, occupying the chair.

Method of Performing the Cuti-reaction.

Dr. HENRY A. ELLIS demonstrated his method of performing the cuti-reaction by making four parallel incisions, drawing blood in each case, on the anterior aspect of the forearm from above downwards, pure P.T.O. being inoculated into the uppermost and into the others successively dilutions of 1/10, 1/100, and 1/500. The reactions are classified as negative; subsensitive, if positive with pure tuberculin and the first dilution; sensitive, up to the second and hypersensitive when all are positive. A subsensitive reaction is a failing reaction and the prognosis is grave, because the case is probably acute and the tissues are unable to respond. So, too, if there be a general reaction without a local one, the prognostic significance is bad, while a high degree of resistance on the part of a woman is a much better sign than it is in a man. A sensitive reaction probably indicates that the case is more or less stabilised, and the clinical findings become of greater value. A hypersensitive reaction indicates that the responsive power of the patient is good and will probably justify sanatorium treatment.

Dr. D. M. BARCROFT emphasised the diagnostic significance of the triad—hæmoptysis, dyspnœa, and progressive loss of weight—in diagnosis, especially when physical signs were absent or uncertain, and Dr. F. HERNAMAN-JOHNSON showed the X ray plates of the same patients and of others, and Dr. CAMPBELL MCCLURE showed other cases. One of the objectives of the dispensary, according to Dr. McClure, is to correlate the findings obtained with the clinical signs and the radiographic appearances. On the whole the results of this "team-work" have so far been encouraging and manifest concordance in about eight out of ten cases, though differences of opinion occurred in interpreting the varying conditions met with in tuberculosis of the lungs. Dr. Hernaman-Johnson stated that he had never seen a case under the X rays of apical tuberculosis without involvement of the hilus, and that, in his opinion, tuberculosis of the lungs was primarily a hilus disease which spread therefrom, fanwise, towards the apices. On the assumption that the striæ which are seen radiating from the hilus to the apex depend for their manifestation upon the deposition of calcium in the walls of the lymphatics, an attempt has been made to demonstrate similar "lines of calcification" from enlarged cervical glands downwards towards the apices, but hitherto without success.—A series of X ray photographs were also shown illustrating difficulties occasionally met with in diagnosis, such as carcinomatous stricture and pouch of the œsophagus, aneurysms, &c., together with a screen case in which, probably as the result of fibroid contraction, the heart had been completely pulled over to the right side. Dr. G. MACDONALD exhibited an extensive case of lupus of the face, which, after a course of tuberculin had failed, was cured by the application of brass-paste.

Cultures of Tubercle Bacilli.

The PRESIDENT showed three cultures of tubercle bacilli of historical interest. The first was the 180th subculture of a bacillus of the human type which he originally obtained from Koch in 1906, the subcultures having been made every month without a break; the second of bovine type from a calf which he obtained from Calmette, then of Lille, in the same year, also in its 180th subculture, and the third of bovine type from a pig which had been given to him by Bang, of Copenhagen, in 1907 and similarly subcultured. All were living and growing true to type, but completely avirulent.

Dr. F. R. WALTERS proposed, and Dr. JAMES WATT seconded, a hearty vote of thanks to Dr. McClure and those associated with him in providing so instructive an evening. It is hoped to hold a series of clinical meetings during the session.

SCOTTISH SOCIETY OF ANÆSTHETISTS.

A MEETING of this society was held on Dec. 4th, 1920, in Edinburgh, with Dr. H. TORRANCE THOMSON, the President, in the chair.

Dr. THOMSON read his inaugural presidential address on

Post-operative Morbidity in Relation to General Anæsthesia.

He said that although many conditions falling into the category named are not directly under the control of the anæsthetist, it is essential that he should be fully acquainted with the literature and current theories of the subject, so that he may play his part in securing improved results. Dr. Thomson reviewed recent work under the three headings: (1) nausea and

(2) chest complications; (3) shock. As to nausea and vomiting recent work did point to some connexion between diminution of alkali reserve and after-vomiting, but that was not the whole problem. The use when possible of nitrous oxide oxygen, smooth administration of the least possible quantity of anæsthetic and gentleness of manipulation on the part of the surgeon, were all factors in its prevention. On the whole, he favoured the preliminary use both of narcotics in moderate dose and of alkalis. As to chest complications he thought that skilful administration was of more importance than the mere choice of anæsthetic. In cases of so-called ether bronchitis or pneumonia he thought the patient usually had a pre-existing catarrh, a point too little recognised by surgeons. Prevention of skin-chilling during operation and transit back to bed also demanded careful attention. The warming of anæsthetic vapours might diminish local irritation of air-passages, but its effects on after-results were not proved, so far as prevention of respiratory complications was concerned. As to shock, the work and literature of the war had shown some connexion between acidosis, falling blood pressure, and clinical shock. It was, however, in cases showing marked diminution of pressure before operation that the connexion seemed closest. From the anæsthetist's point of view such cases should be given gas oxygen. The practical difficulties were the lack of proper plant in many hospitals and the cost and trouble of transporting the apparatus in private work, which would involve raising the standard of remuneration for anæsthetic work. Summing up the whole question, Dr. Thomson thought that the essentials in the prevention of complications were: (*a*) that anæsthesia should never be pushed to a degree greater than was absolutely essential, and that in this respect the surgeon should learn not to be too exacting; (*b*) that Crile's pre-operative anti-emotional technique should be carried out as far as possible; (*c*) that excess in fasting and purgation should be avoided; (*d*) that alkalis and a moderate dose of narcotics should be given before operation.

Dr. H. P. FAIRLIE said, with reference to vomiting, that he was glad to hear a warning regarding the excessive starvation and purgation which are so often prescribed before the administration of an anæsthetic. He agreed that they tended rather to encourage than to prevent post-anæsthetic vomiting. He recalled a measure advocated by the late Dr. Renton—the placing of the patient in the sitting posture after operation. He said that it rendered vomiting less likely to occur, and less objectionable when it did occur. The use of preliminary atropine helped in the prevention of vomiting, and also in the prevention of post-anæsthetic bronchitis, by diminishing the secretions in the mouth which are so liable to be swallowed and inhaled, acting then as an irritant. As to shock, the official publications had impressed him also as being very valuable contributions to the knowledge of this subject and of acidosis. Dr. Fairlie had had considerable experience of gas and oxygen as an anæsthetic, and had found it to be expensive, to require a bulky outfit, and often, especially in abdominal operations, the addition of ether. But he nevertheless agreed that in many operations it was a most valuable anæsthetic. It was safe, it diminished shock, and it left the patient in a much happier state than did ether or chloroform, sickness being less frequent and less severe after gas and oxygen than after either of the other anæsthetics.

Exhibition of Cases.

The PRESIDENT reported a case of a 10 days old child anæsthetised by chloroform-open-ether for an operation lasting a few minutes only. No incident of note during the operation, but the child died suddenly ten days later; post mortem typical status lymphaticus was found.

Dr. D. LAMB recorded a case of Secondary Syncope after breath-holding during an induction by chloroform of a woman some years ago. The respiration began again after the use of artificial respiration and persisted for 40 minutes, although there was no pulse, and with the exception of the chest movement the patient was apparently dead.—Dr. J. S. ROSS said he had seen something of the same in a dog, but never in a human being, nor did the condition persist for more than a minute or two.

Dr. JOHNSTON recorded the case of a woman who had a Pott's fracture reduced under nitrous oxide, and who died ten minutes after recovery from the anæsthetic. Post mortem thrombosis was found in the femoral artery and vein of the affected limb and an embolus in the pulmonary artery.

BRISTOL MEDICO-CHIRURGICAL SOCIETY.

Psychotherapy.

A MEETING of this society on Jan. 12th was devoted to a discussion on Psychotherapy. Dr. L. E. V. EVERY-CLAYTON presided.

Dr. R. G. GORDON said that the time had come to consider how much value can be attached to the three methods of psychotherapy—"suggestion," "persuasion," and "analysis." For hysterical symptoms persuasion was the method of choice. This consisted in giving the patient a full insight into the reasons underlying his condition and encouraging him to employ the function the use of which he has forgotten. It might be found that underlying the hysterical symptom was an anxiety neurosis, and for this analytical treatment was necessary. Dr. Gordon discussed and criticised the methods of Freud and Jung, and those adopted by the English schools, and advocated those expounded by Rivers, Hart, and Ross. He pointed out that psycho-analysis in unskilled hands and unbalanced minds was a dangerous weapon, but that the profession as a whole were not alive to all the possibilities of psychotherapy and often failed to realise how much of the material they have to deal with is functional and curable. The absence of training in medical psychology in the course of the education of the doctor was a serious defect, since at least 40 per cent. of the cases which a general practitioner had to treat were, he said, neurotic.

Professor LLOYD MORGAN pleaded for closer union between academic and clinical psychology, referring to an article recently published by him advocating the teaching of psychology to medical students. He asked the clinical psychologists to "nail their colours to the mast," and to state to which school of psychology they adhered.—Dr. J. R. R. TRIST spoke of the work of a neurological clinic of the Ministry of Pensions, and illustrated the impossibility of separating psychotherapy from other forms of treatment by data regarding the incidence of tuberculosis among neurasthenic ex-Service men.—Dr. H. H. CARLETON referred all conflict to a struggle between the egotistical instincts on the one hand and the higher more recently acquired altruistic motives on the other, and alluded to the importance of the "herd instinct."

Mr. O. H. WOODCOCK confessed himself an adherent of the animistic school of psychology. As a means of preventing psychical disorders he declared his belief in educating the individual to a better understanding of himself and his relation to the cosmic order.—Dr. J. R. CHARLES criticised the philosophy on which modern psychotherapy is founded, pointing out that "conflict" is not merely inevitable but actually necessary as a means of education for the individual and the race. He deprecated the use of hypnosis as a therapeutic measure.—Dr. C. F. COOMBS alluded to the disturbances of visceral function that arise from the psychoneuroses, and also to the part that similar disturbances often play in aggravating the symptoms of organic disease.—Dr. E. T. GLENNY attacked the work of the psycho-analysts, particularly on the grounds that it was falling into the hands of practitioners with inadequate experience of organic disease, and that undue insistence on sexual motives was discrediting the profession in the eyes of the public.—Major A. E. J. LISTER, I.M.S., described the case of an Indian soldier and his recovery from a psychoneurosis by means of auto-suggestion.—To these comments and criticisms Dr. GORDON replied.

Reviews and Notices of Books.

PREVENTION OF VENEREAL DISEASE.

By Sir G. ARCHDALL REID, K.B.E. With Introductory Chapter by Sir H. BRYAN DONKIN, M.D. Oxon., F.R.C.P. London: William Heinemann. 1920. Pp. 447. 15*s.*

THE struggle between the National Council for Combating Venereal Diseases and the Society for the Prevention of Venereal Disease has been watched with interest by medical men and sociologists. Parliamentary debates, articles and letters in our own and other professional journals, White papers, and manifestos have marked its course, but this volume contains the first authoritative and comprehensive exposition of the opposed views. Sir Archdall Reid and Sir Bryan Donkin—who contributes a valuable introduction—are well qualified to produce such a work; it is issued under the auspices of the Society, and is welcome as a statement of the position and tenets of that body. A complementary statement from the Council would be equally welcome; particularly interesting would be the history of the Council's present attitude with regard to immediate disinfection.

It is necessary to realise clearly the standpoint from which this book is written, for an impartial outlook cannot be expected from an author writing in the interest of one side or the other. The work deals primarily with one aspect of prevention; its object is instruction as to "prompt employment of simple antiseptic measures which will effectually destroy the infective agents of syphilis and gonorrhœa before they enter the body tissues and thus definitely prevent the occurrence of disease." In his introduction Sir Bryan Donkin gives a brief résumé of the more recent history of the prevention campaign—by "prevention" is meant "immediate disinfection"—and of the opposition it has met with. He emphasises the present necessity for "a public and unbiased inquiry on the whole matter, including, of course, the official Note to the Minister of Health ...... as well as any subsequent documents on the question which have issued or may issue from the office of that Ministry." Sir Archdall Reid first indicates the urgency of the problem. The figures concerning the civil population need not be discussed, as they are frequently encountered in other publications. He remarks that at the time of the German offensive in 1918 there were in the V.D. hospitals or in the convalescent depôts not only an army corps but a great army of trained soldiers otherwise fit, "complete from almost G.O.C. to trumpeter," all of whom had become diseased after the authorities understood prevention. "These," he says, "were put out of action and the Allied cause brought to the verge of ruin by the fanaticism of a few 'influential people' and the complaisance and timidity of a few obliging officials."

Chapters are devoted to a consideration of "instinct and reason," "development of mind;" and "inclination and morality." The author believes it to be impossible to reach a decision concerning the right and wrong of prevention until we know why some individuals are inclined to be sexually moral and others sexually immoral; his statements under these headings are interesting and stimulating, although we cannot agree with all of them. Opposition to sanitary measures he finds to be based on the contentions (*a*) "that such measures would be ineffectual," and (*b*) "that they would make vice safe and so encourage immorality." He points out that these statements are contradictory, but are reconciled by the assertion (*c*) "that though effective sanitary measures are impossible the public would believe in and practise them with the result that both immorality and venereal disease would receive an impetus." It is the deduction which is in question.

In the author's opinion it is uncertain whether fear acts as a deterrent; we believe it to do so in a very small number of people; moreover, we consider it immoral to withhold knowledge whereby infection may be prevented, lest fear, the last remaining barrier against vice, be removed. It is immoral to bolster up the false morality of those who are restrained by fear, when by so doing protection is withheld from those determined to expose themselves to risks which will in many instances bring suffering and disease to the really innocent. We are glad to see that Sir Archdall Reid exposes the equally immoral attitude of silence as regards sexual matters in dealing with the young; we would, however, suggest that he does not appear to realise the present widespread overthrow of this pernicious reticence. He has also apparently failed to grasp the fundamental importance of the work of the Royal Commission on Venereal Disease. The Commission succeeded to a remarkable extent in the creation of a new atmosphere, to which are practically due the candour and publicity with which sex matters have since been discussed in the councils of the nation, in the press, and in many other ways.

Chapter IX. is devoted to "V.D. in the Army"; we could wish that the author had extended his horizon and given more information, but two important statements appear in this short chapter: (1) owing to a lack of anti-venereal measures the colonial troops suffered so greatly that at one time the Australasian Government were reported to have threatened to withdraw their forces unless better protective measures were taken; (2) in Sir Archdall Reid's own experience existing sanitary measures were, for the first 18 months, practically a dead letter; when the authorities established venereal ablution rooms much good was done, but many cases still occurred. The author lost patience, and, on his own initiative, at considerable risk of official censure or even deprivation of his command, introduced a system of immediate self-disinfection. "Immediately venereal disease vanished from my units. For six months not a single case occurred. In two years and four months, during which quite 20,000 men must have passed through my hands, only seven men were infected. I saw many cases of venereal disease, but these were all among men who had contracted it elsewhere."

"Of these seven cases—six of gonorrhœa and one of syphilis—two were contracted from their own wives by men on leave, two occurred in men so drunk at the time of infection that they had little or no recollection of what had happened, and could only be sure that they had used no antiseptics; one man joined the station late in the afternoon, and contracted disease the same evening. He had received no lecture and had used no disinfectants. The last two men, one of whom developed syphilis, delayed disinfection till their return to barracks, one more than an hour and the other more than two hours after intercourse. They told me that they thought it would be sufficient if they followed official directions and used both the permanganate and calomel."

We are bound to state that when the author gave evidence before the Inter-Departmental Committee the value of his work, which has produced such magnificent results, was subjected to the gravest suspicion. A perusal, however, of his own statements, which can be verified by reference to official figures, and a realisation of the lack of pertinency of questions put to him at the Committee, impress us most strongly with the belief that by means of quick disinfection he achieved results which might with great advantage have been universally used throughout the Army.

The subjects of "comparative statistics" and "civilian treatment centres" are graphically treated. The author contends that no one would attend such centres—that the real intention is for sinners and their millions of innocent victims to stew in their own juice. "What other explanation," he asks, "except an unbelievable degree of folly on the part of the Council, can be thought of?" Without holding any brief for the National Council, fairness compels us to enter a protest against the above inference. Experience has shown that sufferers do attend early treatment centres; and if the intention were to allow retribution to descend on sinners and their victims the logical attitude would be to make no attempt at early treatment, or, as it should be termed, "delayed disinfection." The formation of these centres may be open to criticism, but the statement quoted is neither deserved by those responsible nor worthy of its writer.

The remainder of the work contains an account of the labours of the Inter-Departmental Committee, whose official report should be carefully studied by our readers. Speaking frankly, and without any reference to Sir Archdall Reid, we regard that work as a failure. It must be realised that no member of that body was known to be in favour of early disinfection and many were against it. The report was signed only by the chairman; if there was dissent from the conclusions published nothing of it was made public. Sir William Osler and Lord Dawson were invited to give evidence before the Committee; no mention is made in the Note of their opinions, which have elsewhere publicly and strongly been stated in favour of self-disinfection. An account of the activities of the Society with "Lord Sandhurst's Apologetics" and various interesting appendices are also included.

We sincerely hope that this work will secure the attention it deserves. It is the outcome of the honest efforts and sincere thinking of one who has realised the dimensions of the menace of venereal disease. Two fundamental questions present themselves: 1. Is the author's method for prevention efficient? We believe with full realisation of statements made to the contrary, that there would be no difficulty in instructing the public along these lines. 2. Is it desirable, on the widest grounds, that such knowledge should be promulgated? Here is a difficulty, serious, but not insurmountable. The necessary information should be placed before the public in such a way that suggestiveness is completely avoided; it should be accompanied by the statement that absolute safety lies only in continence, and that promiscuous sexual indulgence is fraught with physical risk, not only to the individual, but to the nation. We thoroughly appreciate the view that information on sex matters should be widely extended to children, but special care should be taken in promulgating knowledge of means of self-disinfection that the young should not be unnecessarily injured. We do not believe that the extension of such knowledge to the public will increase promiscuous sexual intercourse. At the present day the existence of condoms is known to practically all adults, yet many remain chaste, although such appliances are flagrantly available. The object of both forms of protective measures is the same. The public generally already believes in the absolute efficacy which is afforded by condoms. Advice as to immediate disinfection would secure greater provision for their safety without providing increased inducements for promiscuous sexual intercourse. In conclusion, we hope that when the second edition of this work appears its author will see his way to eliminate certain personal, thoughanony mons, references, which, in lack of taste, afford a striking contrast to an otherwise powerfully written and valuable volume.

A GUIDE TO ANATOMY.

For Students of Medical Gymnastics, Massage, and Medical Electricity. By E. D. EWART. London: H. K. Lewis and Co., Ltd. 1920. Pp. xii. + 301. 16*s.*

THIS book, as the title informs us, is intended for students of massage, &c., and is therefore not to be taken as an elementary guide to the whole anatomy of the body. Miss Ewart is well qualified to know the anatomical needs of the class of students for whom she writes, but, surely, some teaching on the situation and association of the ovaries and uterus might be of more utility than short details of *rotatores spinæ* and intertransverse muscles. Such criticism apart, it can be said that the text of this little work appears good and clear and accurate if necessarily abbreviated. The spleen, we observe, has a hilus, whereas the kidney, more accurately, is said to present a hilum. The illustrations are clear, and will serve their purpose satisfactorily, but we notice several errors in detail: thus, the line of the buccinator Fig. 9 gives no area for the gums, the petro-sphenoid suture is out of place in Fig. 11, the psoas is not on the back of the small trochanter, as shown in Fig. 28, nor does the pectoralis minor leave the second rib clear as in Fig. 38. These and similar small inaccuracies do not, however, detract from the utility of the book. Chapters on surface-marking follow each section, and some examination papers are placed at the end.

DIE WURMFORTSATZENTZÜNDUNG.

Eine pathogenetische und histologische Studie mit besonderer Berücksichtigung der Bedeutung der Helminthen, speziell der Oxyuren, und wichtiger allgemeiner klinischer Gesichtspunkte. By Dr. A. RHEINDORF, Prosector am St. Hedwigs-Krankenhaus zu Berlin. Berlin: S. Karger. 1920. Mit 52 Abbildungen. Pp. 244. M.18.

THOUGH helminthic infections of the appendix had been previously noted, it was Metchnikoff (1901) who first drew attention to their ætiological significance in appendicitis. Since these views were expressed two schools of thought have arisen. These are: (1) the followers of Aschoff, whose monograph on appendicitis appeared in 1908, who regard the presence of worms in the appendix as of secondary significance; and (2) those like the writer of the treatise under review, who consider the helminthic infection of primary importance in the production of inflammatory conditions of the appendix.

It is the object of this treatise to establish the view that helminthic infections of the appendix, chiefly those due to oxyuris, and, to a less extent, trichocephalus and ascaris, lead to primary alterations in the structure of the organ, so that secondary bacterial invasion takes place. The author studied a large amount of material in the shape of appendices removed by operation, especially during the war, both from adults and children. In addition, material from individuals killed in the war was also collected. Dr. Rheindorf appears to have conducted his investigations very carefully and has studied the appendices in serial section, the only method which will give reliable information as to the presence or absence of helminths or the lesions they produce. The first chapter of the book is mainly historical and summarises the views held as to the ætiology of appendicitis. In the second chapter are described the various changes induced in the appendix by helminths. The findings are illustrated by excellent microphotographs, which clearly show the lesions produced by the worms. The largest number of oxyuris found in an appendix was 684. Chapter III. is devoted to the clinical aspect of these worm infections. In most cases there are no symptoms, but in certain individuals, who must be assumed to have an idiosyncrasy, definite symptoms arise in the form of irregular febrile attacks, abdominal pains, often localised in the appendicular region, and various neuroses, quite apart from an actual appendicitis. In Chapter IV. the pathology of appendicitis is considered, with special reference to the relationship between the primary helminthic lesions and the subsequent secondary inflammatory condition. Aschoff's view that the latter is primary, and not the result of the changes produced by the worms, is contested, and it is suggested that Aschoff's method of examination led him to overlook the helminthic element in the vast majority of the 1000 cases he studied. In Chapter V. are given figures illustrating the frequency of helminthic infections in men killed during the war in Germany and other countries. In a series of appendices removed at operation oxyuris was found in 50 per cent. of the cases, whereas in the organs from men killed in the fighting oxyuris was found in only 5 per cent. As the author remarks, these figures speak for themselves. Chapter VI. treats of the important subject of prophylaxis. In Dr. Rheindorf's opinion oxyuris is primarily responsible for the overwhelming majority of cases of appendicitis, so that an early eradication of this infection would be followed by an almost complete disappearance of the disease. To accomplish this result an organised campaign against the worm is necessary; the danger of its presence in the bowel must be widely known, and a means must be discovered not only of diagnosing its presence, but of effectively ridding an individual of every trace of the infection.

The treatise is full of interest, and it must be admitted the writer produces facts in support of his arguments. Whether pathologists generally will agree with him remains to be seen. Nevertheless, the views expressed are worthy of careful consideration by all those interested in the ætiology and prevention of such a widespread disease as appendicitis.

MACEDONIA: A PLEA FOR THE PRIMITIVE.

By A. GOFF and HUGH A. FAWCETT, M.R.C.S., D.P.H. London: John Lane. 1921. Pp. 274. 21*s.*

THIS is a curiously simple work. It is evidently written by two young observers to whom the East before their visit was a sealed book, and it records their impressions with a freshness and naïveté altogether delightful. It is a pleasure in these days of introspection and analysis to come across a book in which the writers solemnly record the fact that a tortoise lays eggs or that the Greek Church observances are marked by elaborate ritual. We can sympathise with the writers' pleasure at seeing the primitive Oriental methods of agriculture, ploughing, thrashing, winnowing, and the like; for an observer who sees these for the first time will at once have a clearer idea of the meaning of sundry passages of Scripture and of the whole of the Georgics than he ever had before. But if, when describing things seen the authors are trustworthy, when they wander into the by-paths of history they flounder. It would be difficult to find a more inaccurate statement than the following (p. 179):—

> "The Greek Church as at present constituted was founded by the Roman Byzantine Emperor, Constantine the Great, who, having been converted to Christianity in A.D. 312, lent his support to the orthodox bishops at a great Christian Council at Nicæa (Nice) in the same year."

Now, the Council of Nicæa (the first General Council) was held in A.D. 325, and Constantine no more supported the orthodox bishops at that Council than the King supports either the Conservative or Liberal party at a General Election. The King accepts the verdict of the majority, and so did Constantine. The figures at the Council were: for the insertion of the word "consubstantial" (the orthodox point), 286; against (the Arian point), 17. All that the Emperor did was to confirm the judgment of the Council.

The best part of the book is supplied by the singularly charming reproductions of drawings and water-colours by Mr. Fawcett, and the account of the Plain of the Struma is admirable. It is curious that in their account of the birds the writers make no mention of the crane, the "Strymoniæ grues" of the Georgics.

THE SCIENCE OF EATING.

By ALFRED W. MCCANN. London: Evan Brothers, Ltd. Pp. 408.

IF the statements made by Mr. McCann in this book are true, food conditions in the United States are as bad, if not worse, than they were in this country when, some 70 years ago, THE LANCET entered upon its inquiry into food and its adulterations. It is a pity that Mr. McCann writes in the very worst style of "journalese," for his book is interesting and contains many home truths; but a writer who uses such terms as "kidneycides" and "meatology" is singularly irritating to his readers. (Does anyone recall the veracious history of Mr. Downey V. Green? If so, he will remember Mrs. Cheney's description of Dr. MacGuffin, of Goober Valley, who built up the science of mindology, together with existology and hominology.) However, although Mr. McCann's language be trying, we can go far with him in his strictures on denatured foods, flour that is practically starch, and canned abominations of various kinds. Mr. McCann is severe on those who eat too much meat. In this country, whatever may have been the case in the past, we do not think the population eat too much meat now. Another good point made by Mr. McCann is the wastefulness of throwing away the water in which vegetables have been boiled. Such water should be put into the stock-pot.

JOURNALS.

British Journal of Experimental Pathology. December, 1920. London: H. K. Lewis and Co. 7*s.* 6*d.*—The present number of this journal completes the first volume, which, when bound, will open with an apposite quotation from that wise philosopher, John Locke.—The Ætiology of Epidemic Influenza: Experiments in Search of a Filter-passing Virus, by H. B. Maitland, Mary L. Cowan, and H. K. Detweiler. The authors carried out their investigations during an epidemic of influenza at Toronto in the spring of 1920. In spite of the most careful work no evidence for a filter-passing organism could be obtained.—The Influence of the Reaction of Media and of the Presence of Buffer Salts on the Metabolism of Bacteria, by C. G. L. Wolf. The formation of toxin in cultures of vibrion septique is influenced by the presence of a buffer salt—sodium phosphate. The toxin had a higher potency than the control and a better "keeping" quality.—The Effect of Surgical Anæsthesia on the Reaction of the Blood, by J. B. Collip. The author suggests that during surgical anæsthesia two processes, which are mutually antagonistic, are active, one the "acidotic process" of Haggard and Henderson, due directly to disturbance in metabolism as a result of anæsthesia, the other the "over-ventilation process." Whether the hydrogen-ion concentration of the blood falls, rises, or remains unchanged during surgical anæsthesia would therefore depend upon the relative intensities of these two processes.—Glycogenic Infiltration of the Liver of Laboratory Rabbits, by H. M. Turnbull. This paper is illustrated by two very beautiful drawings, which show that the histological changes seen in ordinary microscopic preparations of the rabbits' liver, when infiltrated with glycogen after a suitable meal, resemble closely those of a severe parenchymatous degeneration.

Journal of Hygiene. Edited by G. H. F. NUTTALL, F.R.S. Vol. XIX., No. 3. January, 1921.—The first paper in this issue of the journal is by G. W. Grabham, M.A., F.G.S., and deals with Some Factors in Thermal Sanitation in the Tropics. The results are given of a number of experiments on the temperatures reached by different coloured cloths and paints exposed to sunlight; the general result is that white clothing is cooler than that of any other colour. The explanations for this are discussed. Texture and translucency of material are also considered.—The Wassermann Test in Patients Affected with Malaria in the Tropics, by F. H. Hehewerth and W. A. Kop. The following results were obtained by the authors: malarial infection causes a positive Wassermann reaction in 50 per cent. of cases in natives; the reaction disappears as a rule under quinine treatment, but may persist three to six months.—Clinical Investigation of Xerophthalmia and Dystrophy in Infants and Young Children (Xerophthalmia et Dystrophia Alipogenetica), by C. E. Block, M.D., Professor of Pediatrics in the University of Copenhagen. A preface to the article is contributed by the Accessory Food Factors Committee (appointed jointly by the Lister Institute and the Medical Research Council). Dr. Bloch by clinical observation arrived at conclusions concerning the importance of certain kinds of fats for nutrition and growths which McCollum reached by experimentation on animals. He gives the term dystrophia alipogenetica to the condition of ill-health which results from deprivation of such fatty foods as butter and milk. Associated with inhibition of growth there is an increased susceptibility and lowered resistance to all infections, including xerophthalmia. The best treatment is the administration of cod-liver oil, but whole milk, butter, eggs, and other fats containing the specific body are also curative. The disease is more common in Denmark than in other countries, the reason apparently being that Denmark exports most of its dairy produce, especially butter. This is borne out in an interesting observation made by Dr. Bloch during the Great War. When the German submarine blockade became established in February, 1917, the import of fodder for cattle was completely stopped. The Danish Government was therefore compelled to take control of all butter and ration it so that everybody, adult and child, was entitled after Dec. 21st, 1917, to 250 g. of butter a week, which was sold at such a low price that all could buy it. From that moment everyone ate butter instead of margarine and since then there has been no xerophthalmia in Denmark. —The Water-supply of the Egyptian Expeditionary Force, with Special Reference to the Efficiency of Mechanical Rapid Filtration with Chlorination, by R. J. S. McDowall, M.B. The water supplied to our troops in Palestine came from the Nile and was rendered potable by rapid filtration and chlorination. —The Chemotactic Effect of Osmosis upon Leucocytes, by F. Maltaner and Ella Hoppe. By means of a number of ingenious experiments the authors show that leucocytes move into solutions of higher density than the solution in which they are suspended. The general rule appears to be that leucocytes move in a direction opposite to that in which dissolved substances are diffusing.—Malaria in England, with Special Reference to the Rôle of Temperature and Humidity, by Lieutenant-Colonel C. A. Gill. This is an interesting communication upon an important subject.

FRENCH SUPPLEMENT TO THE LANCET

Under the Editorial Direction of

Professor CHARLES ACHARD, PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PARIS.

AND

Dr. CHARLES FLANDIN, D.S.O., CHEF DE CLINIQUE A LA FACULTÉ DE PARIS.

RETROLABYRINTHINE INVESTIGATION IN OTITIC SUPPURATION OF THE POSTERIOR CEREBRAL FOSSA.

BY DR. A. HAUTANT,
OTO-LARYNGOLOGIST TO THE PARIS HOSPITALS.

IN the presence of endocranial complications of aural origin otologists are united as to the necessity of including in their surgical interventions the following three processes: evacuation of the original lesion of the middle ear; exploration of the parameningeal lesion which conveys the otitic suppuration to the endocranium; and, if necessary, an attack on the endocranial lesion itself. The most important of these processes is exploration of the intermediate lesion, the link between ear and meninges, because (*a*) endocranial complications are *frequently at the outset only accidents of juxtaposition*, a kind of collateral œdema disappearing upon drainage of the otitic lesion and evacuation of the parameningeal abscess; (*b*) endocranial complications do not arise by chance—they develop at the point where the original lesion comes into contact with the meninges, and the surgeon is guided straight to them by the *intermediate lesion*. It is *generally sufficient to explore* this lesion in two directions: (1) at the level of the roof of the attic and the antrum; (2) at the level of the posterior surface of the mastoid. It sometimes happens that this investigation bears no result; a third means of approach is then employed—the internal ear. This last is a new method only employed for about ten years.

Importance of Suppurating Labyrinthitis.

The signs of invasion of the internal ear by infection (total unilateral deafness and absence of the nystagmic reflex) are often observed in otitis with endocranial complications. Injury of the labyrinth always proves the gravity of the infection, but its presence does not necessarily *imply that the infection has passed from* the tympanum to the endocranium through the internal ear. Whilst attacking the labyrinth, infection may spread to the meninges by means of the roof of the attic or the posterior surface of the mastoid. The establishment of labyrinthitis should not be a signal for neglect of the other routes of infection. It is necessary to point out this restriction of the importance of suppurating labyrinthitis, *for* although its frequency has been justly insisted upon, its importance in surgery of the ear has been overestimated.

These reservations once admitted, suppurating labyrinthitis, none the less, represents an important intermediate stage between infections of the middle ear and of the endocranium, from two points of view: (1) Infection of the labyrinth *often gives rise to* defensive lesions which must be respected, but it can also provoke vestibular abscesses, granulations, cholesteatomata, and sequestra, which call for surgical intervention: (2) labyrinthine infection reaching the endocranium can cause localised meningitic lesions (*a*) in the internal auditory passage, where a kind of intrameningeal abscess is *formed* to which surgical approach is almost impossible, and (*b*) on the posterior surface of the petrosa, behind the vestibule, in the neighbourhood of the endolymphatic sac, an extra- or intra-dural abscess can appear, easily reached surgically, and often constituting an intermediate stage leading to encysted meningitis or to a cerebellar abscess. In this way the retrolabyrinthine region is the third area to demand the aurist's attention in labyrinthine lesions with endocranial complications, if and when he has failed to find the connexion between ear and endocranium in the attic or on the posterior surface of the mastoid.

Anatomical Formation of the Semicircular Canals.

Exploration of the retrolabyrinthine region necessitates resection of the bony mass of the semicircular canals; *for this process knowledge of the formation of* the latter is necessary.

(1) Normally this mass, situate behind the vestibule and within the mastoid antrum, is composed of semicircular canals, notably of the canalis semicircularis posterior and the loop of the canalis semicircularis lateralis. These canals are contained in the labyrinthine capsule, which is of very compact hard bone, well named "petrous"; they are sometimes surrounded by diploëtic tissue, by cells connected with the mastoid cells, or, in exceptional cases, in large, deep, retrolabyrinthine cells.

(2) In a pathological condition two facts are to be remembered: (*a*) in acute mastoiditis the diploëtic tissue, or even the retrolabyrinthine cells, may disintegrate and form a large purulent mass situate behind the labyrinth, sometimes approaching the internal auditory canal and capable of giving rise to an extra-dural retropetrous abscess; these are really aberrant sinuses of the acute mastoidal lesion and have nothing *to do* with the lesions deriving from the labyrinth with which we are now dealing; (*b*) in chronic mastoiditis, during the course of chronic *otorrhœa*, the *mastoidal* cells disappear; a process of condensing osteitis has transformed the diploë into compact bone, and the retrolabyrinthine tissue becomes a bony mass *extending from the vestibule to the cerebellar dura mater.* If this chronic mastoiditis is complicated with labyrinthitis (the osseous lesions of which have extended to the cerebellar *surface of the petrous bone*) the following *three important* levels are encountered behind the labyrinth when approaching the cerebellar fossa from the antrum: (1) the internal surface of the antrum; (2) a very compact bony mass, half a centimetre thick, containing the canalis posterior and the loop of the canalis lateralis; (3) in pathological cases, near the dura mater, at the height of the endolymphatic sac, osteitis and granulations, and sometimes a small extra-dural agglomeration of pus.

Thus the presence of lesions at the level of the retrovestibular cul-de-sac cannot be discovered by any sign during exploration of the cavity of a petro-mastoidal ulcer; these lesions are established by a devious route, infection reaches *the* vestibulum, and by a deeper and retrograde course arrives at the retropetrous region of the endolymphatic sac. They require systematic search; for their presence is determined by a process of reasoning, not by *advancing step by step through* osseous lesions, as is usual in exploration of the attic or of the posterior surface of the mastoid.

Conditions Necessitating Retrolabyrinthine Exploration.

Three conditions are necessary to warrant retrolabyrinthine investigation.

(1) There must be a retrolabyrinthine lesion; this is understood, since in *chronic otorrhœa* infection can *only* reach the retrovestibular region *through* the labyrinth. The lesion may be irritative, but that is not enough. Cholesteatoma of the middle ear may set up erosion and irritation of a canal—as digital *compression on the* eyeball irritates the retina—and may induce intense vertigo. If the nystagmic reflex still exists, the labyrinth is still intact, and there can be no question of opening it, still less of exploring the deep retrovestibular region. The labyrinthine lesion *must* be destructive; *infection* has crossed *the* labyrinth and destroyed it. The absence of the nystagmic reaction proves its destruction. This systematic investigation is necessary; no *functional* sign *gives a clue, for* the "quietest" labyrinthine lesions are the gravest.

(2) Infected lesions of the cavities of the ear must be "re-lit"; the signs indicating this reinfection and the first invasion of the endocranium are headache (chiefly occipital), *rise* of temperature (even very slight), modification of the cerebro-spinal fluid, augmentation of albumin content, hypertension, hyperleucocytosis. In fact, if the lesion is not *reinfected intervention can be limited to the middle ear*, or to the vestibule if necessary; it is useless to explore the retrolabyrinthine region and the posterior cerebral fossa if they give no sign of pain.

(3) No other intermediate lesion must be found, during the operation, *between the cavities of the middle ear and the* endocranium. It is obvious that, if an abscess about a sinus,

or an extra-dural abscess on the roof of the attic, has already been disclosed, it is useless to make a systematic search for a retrolabyrinthine abscess. In the absence of such lesions, the first two conditions named being already present, the vestibulum must be opened and explored, and the vestibular cul-de-sac examined. It is true that the results of this examination will often prove negative. It is not necessarily the key to all unexplained instances of spread of infection from the middle-ear to the endocranium. It must not be forgotten that infection may travel by the internal auditory canal, which is practically unexplorable, or *by the venous or lymphatic channels. However, the* possible existence of a retrolabyrinthine abscess, sufficiently easily accessible, and the results which have been obtained, permit us to advocate a search for it under conditions thus prescribed.

Retrolabyrinthine Abscess.

Lesions encountered in the region of the retrolabyrinthine dura mater are similar in every respect to those observed in the roof of the attic—viz., fistula, osteitis, extra-dural abscess; but empyema of the endolymphatic sac forms an exception. There is here a point of pathological anatomy not yet determined; it may be that pus collects between the membranes of the dura mater without the certainty of a connexion with an endo-lymphatic abscess. In order not to prejudge its histological nature I have called this abscess "retrolabyrinthine." It is a small abscess, never exceeding the size of a large lentil, and always extra-petrous, which latter fact differentiates it from the aberrant mastoidal abscesses always confined to the petrosa. It is also extra-meningeal, never passing the dura mater, and thereby escaping all confusion with encysted meningitis. I have observed five instances of this abscess in about 20 cases of labyrinthine lesion with endocranial complications of otitic origin. About 30 scattered cases are to be found in medical literature.

Technique.

The technique of retrolabyrinthine exploration, although simple enough, is hard to describe.

1. To resect the bony retrovestibular mass and uncover the region of the endolymphatic sac the following procedure is necessary: (*a*) Lay bare the dura mater before and behind the lateral sinus to the entire height of the lateral portion of the sinus; lay back this cerebellar dura mater behind. (*b*) Resect the posterior surface of the mastoid, then, *further in, the posterior face of the petrosa*; the first of these is thin, the second compact and resistant. This resection is done with a drill, or better with a gouge. The operative field is confined by the internal surface of the antrum, and includes the triangular region limited behind by the lateral sinus, in front by the facial sinus, and above by the roof of the antrum. The gouge is first used in a vertical direction from above downwards. The internal surface of the antrum is hollowed out; then the gouge enters the lateral and facial sinuses, working from the apex of the *mastoid towards the middle cerebral fossa*; the bony mass of the semicircular canals is chipped with strokes of the gouge in order to facilitate the following process. (*c*) A retrovestibular furrow being thus hollowed out, resection of the mass of the semicircular canals is achieved by placing the gouge this time horizontally, its back against the bend of the facial sinus, the cutting being towards the dura mater at the centre of the cerebellum. The gouge is worked backwards and forwards at first, and a little inwards and outwards, as though aiming for the torcular herophili. It is then pivoted *about the bend of the facial sinus and directed* towards the occipital foramen; finally, it is directed inwards and outwards definitely towards the basilar occipital process. The posterior surface of the petrosa is resected in proportion, and the dura mater uncovered little by little as far as the region of the endolymphatic sac.

2. The action of the gouge in the second process is facilitated by the following points of indication: (*a*) It pivots round the bend of the facial sinus, remaining always in a horizontal plane, passing by the fenestra ovalis and the loop of the horizontal *semicircular canal. (b) In progressively* resecting the mass of the semicircular canals two orifices are laid bare on the same level, corresponding to the opening of the loop of the vertical posterior canal. But the canal of the vestibular aqueduct passes along the loop of that canal; the opening of the latter then indicates that the resection of the semicircular mass is sufficient. (*c*) The cerebellar dura mater which covers the internal surface of the mastoid and of the petrosa is easily separated until the neighbourhood of the endolymphatic sac is reached, at which point it becomes very adherent. Resection of the posterior surface of the petrosa should then be carried out as far as the dura mater permits itself to hang loose. Where it joins the retropetrous periosteum resection must be stopped; that is the region of the endolymphatic sac. This last point of indication is the most important.

3. This technique is not dangerous; it requires to be executed in strips in order to avoid cracking the petrosa and tearing the dura mater continuously. When the conditions necessitating retrovestibular exploration are fulfilled it must be carried out in one operation complementary to petromastoidal evacuation. It is useless to intervene in two stages with an interval of 48 hours, for the entire process is extra-meningeal, and if properly conducted is not dangerous. Nor need the possible length of the operation be *considered; aural intervention never induces operative* shock.

Conclusion.

Resection of the bony retrolabyrinthine mass constitutes a means of reaching the anterior internal portion of the posterior cerebral fossa. It permits of access to—

(1) Extradural abscesses developing *on the posterior* surface of the petrosa between the lateral sinus and the internal auditory canal.

(2) Cerebellar abscesses very deeply situated; these are the most frequent type, and cannot be reached by any other means—either across the shell of the occipital bone or by the internal surface of the mastoid.

(3) Meningitis, localised or predominant, in the posterior cerebral fossa. By incising the dura mater near the endolymphatic sac the whole cerebral sub-arachnoid space may be drained. This incision, if kept *open by means of a piece of gauze*, sets up an abundant flow of cerebro-spinal fluid, resulting in marked diminution of headache and general symptoms. In a case of streptococcal meningitis under my own care this drainage clearly assisted the cure.

CEREBELLAR ABSCESSES OF AURAL ORIGIN.

BY DR. ANDRÉ MOULONGUET,

OTO-LARYNGOLOGIST TO THE PARIS HOSPITALS.

CEREBELLAR abscesses have a particular interest among the complications of suppurating otitis, as much because of their variable pathogeny as because of the difficulty of their diagnosis—the latter existing in spite of the recognition of symptoms established by modern semeiology of the cerebellum.

Ætiology.

Frequency.—Rare. Bourgeois believed them to be as frequent as cerebral abscesses. At present it is believed that there is about 1 cerebellar abscess to 4 cerebral abscesses; thus Dench[1] has observed 4 cerebellar to 17 temposphenoidal, and Sydney Scott[2] 12 cerebellar to 42 cerebral. In a third of these cases the cerebellar abscesses were associated with other complications—extradural abscess, thrombo-phlebitis of sinuses, meningitis.

Age.—Exceptional before the age of 10 on account of the high position of the antrum; maximum frequency from 10 to 20 for abscesses following acute otitis, from 20 to 30 for those following chronic otitis.

Sex.—Three times more frequent in the male than in the female.

General causation.—Diabetes and tuberculosis play a disputed part in causation of abscesses.

Influence of traumatism and acute diseases.—Cerebellar abscesses have been attributed to the shock occasioned by gouging; this is a disputable point. They sometimes appear after an acute illness—e.g., measles, scarlet fever, mumps, typhoid.

Influence of the form of otitis.—The preceding otitis is nearly always chronic.

Pathogeny.

Consideration must be given to the following points:—

(*a*) *Routes of Infection in the Petrosa.*

1. *Venous route.*—Phlebitis of the venules connecting the middle ear with the sinus lateralis, or of the osseous venules, notably those of the petro-mastoidal canal.

2. *Cellular route.*—Under the influence of attrition by cholesteatoma or of retention of pus infection proceeds, and a process of osteitis destroys the osseous intercellular walls. The pus can also move along the subantral or peri-labyrinthine cells or the petro-mastoidal canal, and overstep at any point the cortex of the posterior wall of the petrosa.

3. *Labyrinthine route.*—This is the route of infection in nearly half the total number of cases: *it can produce a* fistula of the deep surface of the vestibulum engaged with the cerebellar surface, or, more often, a fistula of the posterior semicircular canal; lastly, much has been made

of the infective agency of the aqueduct of the vestibulum with resultant empyema of the endolymphatic sac. It is probable that a circumscribed extradural collection of pus situate on the posterior surface of the pyramid has often been taken for empyema of this sac. It is, however, none the less true that the importance of this deep retropetrous region is considerable in complications of the cerebellar surface; Vautrain, in his paper[3] suggested by Hautant, insists upon the necessity of his systematised exploration when a deep endocranial complication is suspected.

4. *Route of the internal auditory canal.*—A much rarer route. Infection can gain the canal by two routes—by the Fallopian aqueduct, which the pus traverses after breaking down the thin cortex of the central wall, or by the labyrinth, for the meningeal area is known to communicate with the labyrinthine area by the floor of the internal auditory canal. It must be noted that these different routes may combine to spread infection.

(*b*) *Spread of Infection Beyond the Petrosa.*

1. Infection by contiguity, on contact with the diseased bone; external pachymeningitis, then encephalitis and abscess.
2. Venous route; thrombo-phlebitis and abscess.
3. Arterial route; thrombus, then softening and abscess.
4. Lymphatic route; the pus does not permeate the lymphatic vessels, but follows the perivascular sheaths deriving from the subarachnoid cavity, which surround the lymphatic vessels and communicate with the connective tissue.

Pathological Anatomy.

The abscess is generally solitary, as large as a chestnut or walnut, often situated in the anterior part of the lateral lobes, with predilection for the right side. Classically, an abscess of phlebitic origin is antero-external, an abscess of labyrinthine origin antero-internal. More rarely the vermis is attacked. There is frequently a pachymeningitic lesion around the abscess. The thickness of cerebellar substance separating the abscess from the diseased bony lesion is generally minimal.

The contents of these abscesses vary in colour, odour, and consistency. Bacteriologically are found the usual organisms associated with suppuration, and sometimes anaerobes; sometimes, again, the pus is sterile.

The following varieties are to be distinguished:—

(*a*) Diffluent and ill-defined abscesses, the walls of which fade away with no sclerotic reaction; (*b*) limited abscesses, with a clearly circumscribed cavity whose wall is infiltrated with numerous polynuclear cells, and contains a few connective fibres on the side presented to the vessels; (*c*) encapsuled abscesses, with walls so well defined that the whole can be easily separated from the surrounding cerebral substance, like a real sac; this capsule consists chiefly of conjunctive tissue. The cerebral substance surrounding the abscess is more or less œdematous and hyperæmial.

Symptomatology.

The symptomatology is very varied; only an outline of it can be given. Classically four stages of a cerebellar abscess are described.

(*a*) *Initial stage.*—Where there has been a former otorrhœa with attacks of congestion of the diseased ear. New symptoms will soon appear which are not characteristic, and which give rise to more congestion about the ear, pain, and rise of temperature. Presently clearer signs awake suspicion of infection of the posterior cerebral fossa:—

(1) Injury of the labyrinth—either acute diffuse labyrinthitis with intense vertigo and nystagmus, first towards the diseased ear, then, after several days, towards the healthy ear; or chronic diffuse labyrinthitis, often following the former, and distinguishable by classical tests; (2) facial paralysis, supervening spontaneously during the course of otorrhœa; this sign must always give rise to anxiety, but its prognostic value is still more considerable when it is associated with labyrinthitis; (3) paralysis of the external motor oculi: rarer and of less prognostic value, disclosing an increase of cranial hypertension or a circumscribed leptomeningitis. Its association with other elements of Gradenigo's syndrome (trigeminal neuralgia) may indicate spread of infection towards the cellules of the apex of the petrosa (Baldenweck[4]).

(*b*) *Latent stage.*—A more or less considerable diminution of symptoms of the preceding stage is often observed, but careful general observation discloses morbid conditions the gravity of which will be apparent—viz., alteration in the patient's character, access of sadness and psychic depression; moreover the patient complains of a general feeling of discomfort. This latent stage sometimes appears after petro-mastoidal evacuation which induces an apparent improvement of more or less duration.

(*c*) *Manifest stage.*—Whether the precursory symptoms have already caused petro-mastoidal evacuation to be performed, or whether they have not appeared, multiple symptoms soon supervene in a very variable order of sequence; they may be divided into symptoms of suppuration, of hypertension, and of localisation.

1. *Suppuration.*—(*a*) Special attention has been paid to hyperthermia, and hypothermia attributed to the action of an abscess upon the centre of thermic regulation. As a rule the temperature curve is practically apyretic, and the small irregular thermic rises which are observed on the chart indicate meningeal inoculations. (*b*) Wasting is a capital symptom of cerebellar abscess—a symptom which Lermoyez "wished to see written in capital letters in classical treatises." In a few days muscular degeneration is complete. (*c*) Much less characteristic are the gastro-intestinal disturbances sometimes observed—anorexia, persistent constipation, crusted lips. Sometimes fits of shivering indicate the frequent onset of thrombo-phlebitis; labial herpes and local rise of temperature in the occipital region have also been noted.

2. *Diffuse intracranial hypertension.*—(*a*) *Headache* is the most frequent and earliest symptom of hypertension; it can be general throughout the head, particularly in children; oftener it is localised in the occipital region, with irradiations into the nucha, and sometimes also into the frontal region (Logan Turner[5]) or even on the side opposite to the abscess (Lombard). It is generally a dull, continuous, deep headache with a few paroxysmal crises of very short duration; patients compare it to the pressure of a vice or of a leaden bar inside the head; it is a depressing headache which does not compel the patient to cry out, but he may groan heavily at night. More rarely it is intense and intolerable, exaggerated by anything conducive to congestion of the head—cough, effort, reclining position—and then becomes a bursting sensation. It may be exaggerated by pressure on the eyeballs, but not by percussion or palpation of the occipital region; pain in the latter simply indicates a subdural abscess of the posterior cerebral fossa. (*b*) *Vomiting:* Cerebral, without effort; true regurgitation unconnected with alimentation; sometimes a type of uncontrollable vomiting (Courjon[6]), at other times simple nausea. (*c*) *Retarded pulse:* The pulse is of regular strength and normal amplitude but slackened; it only becomes quickened in the terminal period. (*d*) *Retarded respiration:* Parallel with the bradycardia; in the terminal phase it is accelerated and becomes superficial and irregular. (*e*) *Psychic disturbances:* At the outset mental inertia, cerebral torpor, liability to fatigue, diminution of psychic faculties. Later the patient sinks into stupidity, replying to questions slowly in a tired manner and with a low voice, and being indifferent to his surroundings; he remains for long hours motionless, with eyes half closed. Asthenia becomes complete, and muscular weakness is extreme. Much more rarely phenomena of cerebral excitation are observed; the patient becomes agitated, rises from his bed, and tears off his dressings; in exceptional cases there is melancholia with delirum, necessitating detention of the patient. (*f*) *Generalised convulsions and contractures:* Convulsions are chiefly observed in children; sometimes epileptic crises arise. Contractures are frequently localised in the muscles of the nucha. Stiffness of the nucha, with a drawing backwards of the head, is sometimes seen in cerebellar abscess due to compression of the spinal marrow by the abscess. (*g*) *Lesions of the optic disc and ocular disturbances:* Papillary lesions should always be systematically investigated when deep endocranial complication of otitis is suspected. Congestive vascular disturbances, venous dilatation of papillary stasis or of optic neuritis, may be observed. Absence of these lesions must not, however, occasion rejection of a diagnosis of cerebellar abscess, for they do not appear in a large number of cases (Lundberg,[7]; Dench; and two of the writer's own cases).

3. *Localisation.*—(*a*) Functional symptoms demanding the clinician's notice: (1) more or less intense vertigo, with several special characteristics; frequently a drawing sensation on the infected side. The vertigo is not increased by closing the eyes, nor by increase of pressure in the external auditory canal. It is increased by decubitus on the healthy side; so the patient lies with knees drawn up, on the side of the lesion. It is diminished in the horizontal position. (2) Disturbances of equilibration precede and follow vertiginous cerebellar disturbances. When the patient stands upright—which is not always possible—he moves his feet apart to widen his basis of support; body and head may show more or less distinct movements of oscillation. In Romberg's position it is observed that occlusion of the eyes does not increase disequilibrium; that the fall is usually towards the side of the lesion; that there is no constant connexion between the sensation of falling and the sensation of nystagmus. In walking the legs are widely separated,

and there are festination and titubation. The gait is that of a drunkard, advancing with small steps; the feet are drawn up and set down quickly; the oscillations of head and trunk increase. (3) Nystagmus in either direction—towards the healthy or the affected side; it is often accentuated when the eyes are turned towards the affected side. It tends to increase, not to diminish, as the condition develops. Lastly, it may be modified by excitation of the labyrinth (caloric or rotatory tests).

(*b*) *Motor sensory and reflex disturbances*: (1) Motor disturbances. In many cases paralysis of members of the affected side is observed; this constitutes a clear sign of cerebellar abscess (Damade and Boisserie, Lacroix,[8] Labouré[9]). More rarely double paralysis is observed, due to compression of the pyramidal nerve-tract at the level of the pons; in reality it no longer concerns in this case a focal system, but a symptom produced at a distance. De Stella[10] has reported a case of double paralysis (left side of face and right limbs) with a true cerebellar abscess. Conjugate deviation of head and eyes to the unaffected side has been observed, sometimes ptosis; disturbances of speech, the latter being scanned, with brusque emission of syllables separated by pauses; in exceptional cases there are trismus and difficulty in swallowing. (2) Sensory disturbances, generally absent. (3) Tendon reflexes are generally exaggerated on the affected side.

These different elements sometimes combine in syndromes, of which the most distinct are Brissaud's syndrome (cervico-occipital headache, strained attitudes—e.g., retraction of head, conjugate deviation of head and eyes, disequilibration), and Acland and Ballance's syndrome (exaggerated knee-jerk and sluggishness of lower limbs on affected side, conjugate deviation of head and eyes).

(*c*) Cerebellar tests: A new series of tests has been established in the light of modern knowledge resulting from Babinski's work on the physiology of the cerebellum: (1) Test of routine movements; the patient is told to touch the end of his nose, and his finger passes it. This excess is particularly marked when the movements are made with rapidity; it is not increased by closing of the eyes, and the movement retains its direction and intentional orientation. (2) Test of asynergy—the loss of ability to accomplish simultaneously the various movements which constitute an action. The patient lies down with arms crossed, and is told to sit up. Instead of keeping his legs still he flexes his thighs strongly upon the pelvis, and lifts his heels off the bed. (3) Test of adiadokokinesis—diminution of the faculty to execute movements in rapid succession. (4) Voltaic vertigo test. In the transverse bipolar test—i.e., setting the positive and negative poles symmetrically before the tragus—a rotation of the head is produced, with inclination backwards or always to the same side, whatever the direction of the current. (5) Indication test. This can be applied at different points of articulation—wrists, elbows—but is most easily carried out at the shoulder, by telling the patient to stretch his hands straight in front of him, with extended index fingers. Two kinds of phenomena may then be observed: 1. Spontaneous movements of reaction at the *extremities*; in cases hitherto observed the spontaneous movement has always been made outwards and from the affected side—i.e., with a left cerebellar abscess the right index finger remains immobile. 2. More often the spontaneous reactions are absent; and search must also be made, for presence of movements provoked by reaction, by physiological excitation of the vestibule. Normally, caloric *excitation of the right* ear with cold water results in displacement of the index finger towards the right (this in the position above described). With right cerebellar abscess the left index will travel well to the right, but the right index will remain immobile. If the right labyrinth is destroyed by suppuration the left labyrinth can be used; the opposite reaction will be obtained.

An important *point is that the position* of the articulation at the moment of the test does not influence the direction of the movement; whether the hand is in pronation or supination it is always carried in the same direction during the test.

Final stage.—The duration of the preceding period varies greatly, between a few weeks and three years; as the symptoms become aggravated, emaciation becomes extreme, and death supervenes either by increase of intracranial pressure and progressive coma or by bulbar compression and respiratory syncope (Alt[11]), or again by opening of the abscess into the meningeal cavities.

Evolution after Operation.

Soon after operation there is diminution of the general signs of intercranial hypertension. If coma was present it also disappears shortly, and there is regression of lesions of the fundus oculi; the pocket of the abscess fills up by disappearance of the walls and by granulation, *and in from four to eight* weeks can be healed. Large abscesses may heal without sequelæ. Unfortunately, improvement is often only temporary. Encephalitis is more or less rapidly developed, accompanied sometimes by hæmorrhage which hastens the fatal termination, sometimes by production of a cerebral hernia, which is often symptomatic of a second abscess arising in a diverticulum of the first abscess. Lastly, there is a possibility of recidivity, as in Poli's case,[12] where death occurred from a second cerebellar abscess four and a half years after cure of a first abscess.

Clinical Forms.

(*a*) Symptomatological forms: typhoid, delirant and latent, in which last even very careful examination may elicit no symptom at all, and of which the diagnosis is only made at autopsy; the writer has recently observed such a case. (*b*) Evolved forms: acute or chronic. (*c*) Forms differentiated by age; in the aged a latent or torpid form. (*d*) Forms according to pathogenic organism; the pneumococcus gives chiefly encapsuled abscesses; (*e*) forms complicated by thrombo-phlebitis (Wildenberg[13]), by meningitis, or by cerebral abscess.

Positive Diagnosis.

It is obvious from the multiplicity of symptoms how *complicated and difficult to interpret the clinical picture* may become. The following four tests, of unequal value, are of assistance:—

1. *Lumbar puncture.*—This process gives information as to (*a*) the hypertension of the cerebro-spinal fluid, which is measured by Claude's manometer—a hypertension which is moreover inconstant; (*b*) the meningeal reaction around the cerebellar lesion; the latter is variable, giving now a normal liquid, now albumino-cytological dissociation, now a slight leucocyte reaction, now abundant polynuclear cells, whether altered or not. Borries[14] insists upon what he describes as the "benign picture of the cerebro-spinal fluid"; by a first puncture a cloudy liquid containing micro-organisms and polynuclear cells; in later punctures the polynucleosis is diminished, whilst the bacilli disappear. Borries attributes this to "second-hand" meningitis, betraying evolution of a cerebral or cerebellar abscess.

2. *Hæmatological examination.*—For Sebileau a leucocytosis of 9000 to 15,000, with 70 per cent. polynucleosis, would be the differential count of an encephalic abscess.

3. *Radiography.*—Radiography gives no information.

4. *Aspect of lesions during intervention.*—This constitutes one of the most useful signs; the gouge follows the lesions, which extend backwards towards the posterior cerebral fossa.

Study of all these symptoms admits the assembling of a group of facts favouring the existence of a cerebellar abscess; *investigation by means of puncture is* well advised; except in cases where the abscess communicates with the lesion of the ear it is the only formal means of diagnosis of a cerebellar abscess.

Differential Diagnosis.

We are not now considering those cases where otorrhœa has gone unrecognised owing to insufficient examination; in such cases the most fantastic errors can be made. Here it is understood that otorrhœa has been diagnosed.

1. Otorrhœa as a complication not of otitis, but of an intercurrent disease—typhoid, pneumonia, tuberculous meningitis, cerebral tubercle, cerebellar hæmorrhage, intracerebellar cysticercus, uræmia, or hysteria. Moure[15] has recently reported cases where in the course of otitis media with suppuration symptoms such as nystagmus, torpor, &c., gave rise to the belief that a cerebellar abscess was present; in reality it arose from gingival syphilis which was cured by *treatment.*

2. Otorrhœa as a complication of otitis:—

(*a*) As soon as coma appears the presence of auricular suppuration suggests an encephalic complication; puncture of the cerebrum is then resorted to; if no result is gained it is followed by puncture of the cerebellum; (*b*) if the vestibulo-cerebellar syndrome is absent the following possibilities should be *eliminated: (1) hysteria, persistence of pain after* intervention in neuropathic cases (Bourgeois); (2) otitic hydrocephalus, a sort of œdema of the meninges and of the cerebrum around the affected petrosa, well described by Passot.[15] These phenomena have often wrongly suggested cerebellar abscesses, and futile punctures of the cerebellum have been carried out (Hunter Tod,[17]). Rapid improvement after drainage generally permits the diagnosis; it can sometimes be suspected when lumbar puncture has brought about immediate and complete cessation of the symptoms. (3) Otitic meningitis: the diagnosis is the more difficult in that the two affections can exist side by side, and, moreover, there are forms of localised meningitis of the posterior cerebral fossa with a symptomatology very similar to that of cerebellar abscess. Study of the thermic curve, lumbar puncture, and the cerebellar tests assist in making the diagnosis. (4) Extradural abscess can present symptoms very like those of the cerebellar form. Baldenweck insists upon pain on pressure in the occipital region, characteristic of extra-dural abscess. (5) Phlebitis of the sinuses. The spiky temperature curve and the presence of intense shivering and of pyohæmic complications are the soundest bases for diagnosis; but the two diseases can co-exist. (6) Cerebral abscess. Diagnosis often very difficult. It must be remembered that *nystagmus is frequent in cerebral abscess.* Aphasia is a marked sign of the latter; examination of the lesions in the course of evacuation is most often the best diagnostic indication.

3. There still remains the vestibulo-cerebellar syndrome. Acute labyrinthitis will be present; diagnosis will be difficult, as the two diseases can co-exist or succeed one another. Careful study of the symptoms common to both reveals sufficiently definite differences (Lamois,[18] de Stella [19]).

(*a*) Acute labyrinthitic nystagmus presents a regular evolution. For two or three years it strikes towards the affected ear; at the end of that time caloric excitation of the vestibulum shows it to be more responsive. Then it changes direction, attacking the sound side, the vestibulum becoming unresponsive to hot or cold water. Cerebellar abscess must be considered whenever there is irregularity in evolution of *nystagmus and in excitability of the* labyrinth—e.g., in the following cases: (1) Nystagmus towards the affected ear; 48 hours later, change of direction towards the sound ear; then persisting without modification. (2) Nystagmus for several days towards the sound ear again turning to the affected ear, the vestibulum on the affected side being unresponsive. (*b*) Disturbances of equilibration. The body falls in the direction opposite to that of the nystagmus, and is modified by the situation of the head. In a case of right labyrinthitis with nystagmus towards the left, the patient tends to fall to the right; but if told to turn his head to the right he will fall backwards. This is important, since the cerebellar disturbance is more of equilibration than vertiginous, whilst labyrinthitis is more vertiginous than of disequilibration, and the disequilibration is increased when the eyes are closed. (*c*) In labyrinthitis vomiting does not last longer than two or three days. (*d*) Headache is unknown in labyrinthitis. (*e*) Galvanic test; the bilateral unipolar test, carried out by placing the negative electrode on the nucha and two positive electrodes in front of the ears, induces a fall to the side of the sound labyrinth, whilst the patient with cerebellar abscess, whose intact labyrinths are equally galvanised, does not fall. (*f*) Lumbar puncture shows intact cerebro-spinal fluid in labyrinthitis.

Treatment.

Treatment is purely surgical, and consists of opening the abscess. With regard to anæsthesia, surgeons who during the war observed the danger of chloroform in trephining for wounds of the head became accustomed to using ether; but to avoid the danger of intercranial hypertension induced by ether it is well to precede the operation with a lumbar puncture.

Method of approach.—Authorities are divided as to the best method. (*a*) Some follow the lesions and approach the cerebellum by the mastoidal route, breaking down the posterior wall *of the petrosa and advancing in front* of the lateral sinus, or through it when it is thrombosed (Calamida [21]). (*b*) Others approach the abscess directly by the retro-sinuous occipital route, passing through healthy tissue (Aboulker,[22] Pierce,[23] Curtillet and Aboulker [24]). The chief advantage of this method lies in the harmlessness of futile punctures of the cerebellum made across healthy uninfected tissues. Where a cerebellar abscess is suspected an exploratory cerebellar puncture can thus be made. Lastly, by this method it is easier to supervise the cicatrisation of a cerebellar abscess once the latter has been opened. Opponents of this method say that to open an abscess by crossing a healthy meninx is to risk provocation of a generalised meningitis. *I have been able to demonstrate that this* fear is unfounded,[25] and that the formation of a "cerebral plug" is sufficient to isolate the meningeal space from the cavity of the abscess. (*c*) Combined method—mastoidal with an occipital counter-opening—successfully employed by Luis Suñe y Medan.[26]

Puncture of the cerebellum.—The dura mater has been largely laid bare; its characteristics must be studied. In some cases a small fistula, from which escape drops of pus [illegible] after cleansing, indicates the presence of an abscess; in other cases delicate palpation discloses an abnormal resistance, a characteristic thickness. These are the only certain signs of an abscess. It is better not to *take into account the cerebral pulsation, since some authors consider an increase in the rate to be characteristic of an* abscess, whilst others say the same of a diminution. In exceptional cases there is a cup-shaped depression in the dura mater, as though the latter has been drawn in by the abscess. Soon after the dura mater has been incised the cerebellum prolapses; the latter is punctured, either with Horsley's pus-finder or with aural forceps, the blades of which are parted, or with a hollow sound; the majority of writers have abandoned Preysing's bistoury and Wicart's trocar. Once the pus is *found the forceps are* thrust into the cavity of the abscess and withdrawn with the blades parted. Several writers advise digital exploration of the abscess. Waggett [27] goes so far as to advocate digital search for the abscess.

Dressing and drainage of the abscess.—All writers agree in rejecting drainage by rubber tubing, on which the beating of the cerebral pulse tends to destroy the cerebellar parenchyma. *Gradenigo [28] employs a special encephaloscope.* The floor of the abscess *can also* be touched with various topicæ; most writers have abandoned lavage of the abscess. The school of Saint Antoine, with Mons. Lermoyez, advocate evacuation of the abscess, twice daily, with Péan's forceps or with a long speculum, followed by flat dressing, without the introduction of gauze or drain of any sort.

Vaccinotherapy.—As a result of the work of West autovaccinotherapy has been practised by Stoddart Barr.[29] I am at present studying the action of auto-vaccines in nutritive media with cerebral substance added. This method, intended to conserve the histological affinity of microorganisms for cerebral substances, has been successful when applied to treatment of encephalitis following cerebral wounds caused by projectiles.[30]

Prognosis.

The prognosis is "fatal" when the abscess is *left to* evolve naturally. The most *favourable* statistics *of* operative intervention give about 25 per cent. *of* cures. West [31] is *of* the opinion that the prognosis *of* abscesses following pyo-labyrinthitis is worse than that *of* those following thrombo-phlebitis *of* the sinus.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 5, 1921.

The Health of the Teacher.

Mr. RALPH WAGER, of the Department of Biology at the Northern Illinois State Normal School, has been making an inquiry into the health of school teachers and training college students, and he has come to the conclusion that enough is not done to safeguard the health of the teacher either in the training college period or in later employment. His deductions are interesting, although the smallness of the numbers dealt with does not allow us to draw any wide deductions from them. He finds that of 257 students aged 18 to 21 a large percentage were suffering from remediable defects. Forty per cent. had carious teeth, 28 per cent. defective vision, 8 per cent. ear trouble, and 2 per cent. were suffering from abnormal lung conditions. Attention is drawn to the lowness of this last figure. Not long ago, Dr. WILLIAM OLDWRIGHT, Professor of Hygiene in Toronto University, found that out of 1000 deaths of female teachers from all causes 396 were due to pulmonary phthisis, the mortality-rate being about that of printers (398), more of whom succumb to this disease than do any other class of worker, and higher than that of stone-cutters and saloon-keepers.

In England, the teaching class is very much more carefully selected than in America. The Board of Education insists on an examination for medical fitness before entering the training college. Trainees undergo a medical examination each year of their college life, and, finally, a thorough examination is made before they are employed in State-aided schools. All remediable defects are rectified, over-strain is noted, and consequently there is a thorough weeding out of the unfit. From the Registrar-General's reports the mortality of the male school teacher under 45 years of age appears to be below that for all males in selected healthy districts, while above 45 years the rates occasionally exceed that standard. On going more closely into the subject we find that although the comparative mortality from phthisis of occupied and retired male school teachers generally is 113 per 1000 dead—double that of the clerical profession, and considerably below that of occupied and retired males generally, which is 186 per 1000 dead—it is very high considering that these lives are selected on a health standard. Denmark's example in retiring on a liberal pension teachers who have contracted tuberculosis, or giving them long leave of absence on part pay, might well be followed. Of course, a low mortality-rate is quite compatible with a high morbidity-rate, and it is significant that the maximum mortality-rate for teachers is reached 10 to 15 years later than for the general population, a fact which along with Mr. WAGER'S figures would seem to show that the disease is an outcome of conditions of work. Dr. HANS MEIRHOFER found that in Zurich during the years 1912–14 there were 592 teachers' notifications of illness. Of these, 177 were due to respiratory disease (chiefly laryngeal or bronchial), 107 to nervous troubles, 52 to heart weakness, 53 to infectious disease, 78 to digestive troubles, 60 to diseases affecting bones, joints, and muscles; while under the heading "various," which included anæmia and general debility, were classified 45. The proportion of sick women was more than twice that of men. The large preponderance of nervous and respiratory affections will occasion little surprise when we remember the constant strain to which the elementary school teacher is subjected. She is shut up all day with a class of possibly 60 children. Her point of attention is constantly being diverted, never allowing of concentration for any length of time. Indeed, she may eventually lose this power altogether, and she often becomes fussy, over-anxious, and nervous. She rarely sits; for the greater part of her school day she is standing, breathing an atmosphere of stagnant warm air laden with particles of chalk, fibres of clothing, and exudations from 60 children. The average school teacher dislikes the cool atmosphere of a well-ventilated room, and more often than not in the more modern buildings one finds the means of cross ventilation tightly closed.

The remedy lies not only in a closer adherence to the hygiene syllabus of the training colleges (in England now it is a comprehensive one) and in the reduction of the numbers in classes, but also in the growth of the open-air type of school, which is cheaper to build and easier to alter, and better for teacher and taught than the old permanent variety. Shop assistants in England, by a wise law, are encouraged to sit down to their work when possible. The teacher is directed in the training college to teach in the standing position. It may be that 60 children cannot be controlled otherwise, but it is trying and, among other things, conducive to flat-foot, so common in this profession. An unhealthy teacher is a distinct monetary loss to any education authority. The personality of the teacher is often of more educational value to the developing mind of a child than all the formulæ that are taught, and an effective personality is not found in an over-tired and over-strained frame. Here in England we differ from America in getting teaching material certified physically sound, and for the sake of those to be taught, if for nothing else, we ought to keep our stock of material in good condition. We must lessen the over-pressure and examination evil in secondary schools and training colleges, and we must take every means to prevent over-strain and fatigue by insisting on the ordinary laws of general hygiene being practised as well as preached. For instance, how many cases of over-strain and breakdown are due directly or indirectly to ignorance of voice hygiene? Comparatively little attention is paid to this subject, which ought to be a compulsory one in every training college. It is a curious fact that although the teachers' voice is more or less in constant use, and is the principal medium for the practice of their profession, few teachers know how to preserve the voice by proper use. Indeed, few have any knowledge that there are right ways and wrong ways of using it, and the majority of teachers are *ignorant of the fact that expenditure of* effort and energy can be considerably curtailed by pitching the voice differently for different purposes. The late Dr. E. S. YONGE examined the throats of 100 women teachers in Manchester, and found 70 per cent. with pathological change; 31 of these 70 had definite lesions of the vocal cords. These pathological throat conditions, produced most of them by ignorance, result very often in periodic loss of voice and always in fatigue, which reacts upon the children individually.

What of teaching from the teacher's point of view? That teaching as a profession is not attractive can be gathered from the falling-off in the numbers of men and women who go in for it. Other openings are developing for both men and women, and teaching is going by the wall. The reasons are not far to seek. Apart from conditions of pay, the social life of the teacher is limited. Most of the life is spent among children, and entertaining though interchange of ideas with children may be, it is not very stimulating intellectually; consequently mental atrophy is apt to set in. Teachers, too, women especially, are apt to suffer from over-strain—emotional over-strain rather than intellectual. Apart from all this, the outlook is depressing. If a woman teacher over 40, when her powers ought to be at their maximum and her value in any other calling would be recognised, happens to fall ill, or for any other reason decides to give up work, she will find when she desires to resume again that, apart from reasons connected with superannuation allowances, her chances with appointment committees are poor as against that of the young woman between 20 and 30 not long out of college. There is something wrong in the system when a life of monotonous drudgery under unhygienic conditions is also poorly rewarded and in precarious circumstances. Although conditions here are better on the whole than in America, much productive energy might be spent in both countries in alleviating the teacher's lot, and in making the teaching profession a more attractive one all round.

◆

The Pandemic of Influenza, 1918-1919.[1]

A REPORT on the pandemic of influenza, 1918–1919, has been issued by the Ministry of Health, being No. 4 of the valuable series coming from the Ministry, and dealing generally with public health and medical subjects. The price of the Report is high, but the book is a large closely printed volume, accompanied by the illustrations, maps, and diagrams necessary to its comprehension, while its message is timely as well as of great general value. The responsible authors are Dr. M. B. ARNOLD, Dr. THOMAS CARNWARTH, Dr. S. M. COPEMAN, F.R.S., Dr. BRUCE LOW, Dr. S. P. JAMES, Dr. MAJOR GREENWOOD, and Dr. J. R. HUTCHINSON, attached to the Ministry, aided from without the bureau by, among others, Sir FREDERICK ANDREWES, F.R.S. (professor of pathology in the University of London), Dr. JOHN BROWNLEE (director of statistics to the Medical Research Council), Dr. F. S. CARSON, Dr. HERBERT FRENCH (physician to Guy's Hospital), and Dr. G. W. N. JOSEPH, Dr. A. J. LAIRD, Dr. MORLEY MATHIESON, and Dr. JAMES NIVEN, respectively medical officers of health for Warrington, Cambridge, South Shields, and Manchester. The Report is prefaced with a general survey of the epidemic by Sir GEORGE NEWMAN, chief medical officer to the Ministry, and it is the first intensive study of the scourge that swept across half the world some two years and more ago, claiming a larger total of victims than fell during the whole of the war.

The issue of the Report has been called timely, and this leads us to hope that all who are officially concerned in erecting and maintaining our defences against epidemic disease, will study the terrible story of 1918–1919 in the light of future and organised activities that may be demanded of them. The American who reminded his constituents that "if our foresight was as good as our backsight we should be wiser by a d—n sight" was not belittling, but recommending the study of collated experience, and in the matter of influenza such study may save a vast amount of mortality and misery. True, the deaths from influenza have not exceeded the normal for the last two years, but we must not—neither the public nor the medical profession—build too high on the fact. The disease is now known to recur in successive waves, and we have to face the serious question whether this country is prepared with the knowledge and the weapons whereby to contest a return of the epidemic. For undoubtedly circumstances favour the return of influenza. The compilers of the Report state their view of the matter impressively, if a little obscurely, when they say:—

> "The conclusion to which we are led is that the generation of a great pestilence such as influenza or pneumonic plague is dependent upon disturbance of social order involving for absolutely large numbers of human beings the endurance of conditions of insalubrity which afford for invading parasites a suitable field of modification. ...... No impartial spectator can doubt that at the present time, and almost certainly for a generation to come, there will exist in many nations and over wide tracts of country precisely the type of misery which we suspect to be the appropriate forcing house of a virulent and dispersive germ."

We believe this warning to be warranted by facts, and welcome from the Ministry of Health a Report which, while resuming the past, gives wise counsel for the future. In the light of this Report one of the first tasks for the International Health Bureau will be to track down the epidemic focus of influenza and arrest the disease at its source. Influenza breeding can no longer be tolerated in a world which boasts of a collective health conscience.

◆

Ill-judged Economy.

THE rise and progress of the science of industrial medicine, its importance to our great working centres, its influence upon human endurance, efficiency, health, and contentment, and especially the invaluable work being conducted by the Industrial Fatigue Research Board, have steadily been placed before our readers. We recognised the appointment of the Board, with a mission to extend and pursue investigations which had been successfully set on foot during the war, as a piece of wise statesmanship. The Board has overcome the initial difficulties, which have been considerable, in getting together a staff of expert investigators and in educating new workers. Such reports as have already been issued have been eagerly welcomed, not only in this country, where employers and employees alike are wishful to reorganise conditions of labour on a scientific basis, but also in the United States, France, Canada, Spain, and Italy, where steps are being taken, or being contemplated, to follow our lead. As in the case of the dye industry, our men of science are ahead of the world; are we again going to leave the harvest to others to reap?

---

[1] Report on the Pandemic of Influenza, 1918-1919 (Reports on Public Health and Medical Subjects, No. 4). H.M. Stationery Office. 576. Price 15s. net.

We understand that a decision has been given to cut short the work of the Board at a time when every effort must be put forth to make industry as effective and as healthy as possible. Nor is this all. The Board, originally appointed at the desire of the Home Office, owes official allegiance to the Medical Research Council, and when that Council presented the budget for the coming financial year, the allocation for the Industrial Fatigue Research Board was unconditionally refused by the Treasury. The Board, after balancing the present imperative need for economy with the national importance of the work entrusted to its care, had reduced its requisition to £18,000, but its modesty met with no reward. The decision of the Treasury appears to have been given without investigation of the work of the Board, or any consultation with its members, without any reference to employers and employees, or to the Home Office, whose representatives sit on the Board, or to the Ministry of Health who are naturally interested in medical research and are represented on the Board, or to the Ministry of Labour, who are concerned with industrial contentment and efficiency, and are also represented on the Board. The Chairman of the Industrial Fatigue Research Board is Professor C. S. SHERRINGTON, President of the Royal Society, and among its members are such well-known men in the industrial world as Mr. W. L. HICHENS and Mr. KENNETH LEE, and such scientists as Sir JOSEPH PETAVEL, Professor E. L. COLLIS, Dr. C. S. MYERS, and Professor WINIFRED CULLIS, all of whom give voluntary and unstinted service. We may fairly inquire whether the Treasury is the authority to decide the value and usefulness of any form of medical research, and to do so without inquiry or hesitation. We believe that reduction in the estimate put forward was not asked for, only a curt refusal for the whole sum was sent to the Medical Research Council.

Economy is the plea for this action. It is the sort of economy which makes practical men despair. National wealth depends upon human efficiency in industry. The study of human activity and of the effects of fatigue has in the past been sadly neglected, and the Industrial Fatigue Research Board was removing this reproach. It has, among other things, already pointed out how ventilation may increase output, how rest-pauses scientifically used may improve productivity and increase earnings, how shortened hours may be hygienically and economically beneficial, how industrial accidents, sickness, and activity are influenced by relatively small alterations in temperature, and how intimately certain processes depend on human efficiency. In a little over two years the Board has issued reports relating to the manufacture of shells, the silk industry, foundries, the manufacture of tinplates, cotton spinning and weaving, the boot and shoe trade, and the manufacture of iron and steel, which latter, the *Scotsman* states, "presents a picture of the whole intelligence in the industry engaged in the engrossing pursuit of metallurgical problems to the almost complete exclusion of the factor of human health." We find ourselves in complete agreement with our contemporary that dismissal of the Industrial Fatigue Research Board "is a form of economy which can only, and probably within a short time, involve industry in a good deal of avoidable loss." Then taxation will yield less, while its burden will press heavier.

Annotations.

"Ne quid nimis."

TRINITY COLLEGE, DUBLIN.

THE Report of the Royal Commission appointed last March to investigate the claim of Trinity College, Dublin, to financial aid from the State was published recently. It is strongly in favour of such aid being given, and recommends a non-recurrent immediate grant of £113,000 and an annual subsidy of £49,000. At present the College receives no Government grant, and apart even from its heavy losses during the war, it has insufficient resources to develop in proportion with its needs. Among the most pressing necessities are additional laboratories for pathology and chemistry. In addition to supporting the demands of the College for money, the Commission makes a number of far-reaching suggestions concerning the organisation of the teaching staff. Up to the present not only has the great part of the teaching in Arts been in the hands of the Fellows, but they held the preponderating influence in the life and affairs of the College, the Professors being ancillary. The suggestions of the Royal Commission appear to contemplate a reversal of this position. The Professors will become the predominating power and the Fellows will have a secondary position. This is made clear by the proposals as regards stipends. A whole-time professor is to receive a salary of £1000 or, if he is head of a department, £1300. The junior Fellows, on the other hand, are to be content with stipends beginning at £440 a year and reaching a maximum of £690. They have, naturally, pointed out "that these salaries are quite insufficient in view of the increased cost of living," and they demand that "if a State grant is obtained from the College ...... a further increase in the salaries of Fellows should be made a charge on the grant," but their protest and demand received no support from the Commission. With such inadequate salaries it is bound to be increasingly difficult to attract suitable candidates to the Fellowship of the College. The Commission makes various suggestions concerning the medical and other schools as regards more adequate remuneration for assistants in the faculties. It is proposed also to get rid of the anomaly of the present position of the chair of Institutes of Medicine. The professor of that subject is appointed by the Royal College of Physicians or the foundation of Sir Patrick Dun, but he is, for all practical purposes, a whole-time officer of Trinity College. The Commission proposes that he should, in fact, become so. The Commission makes a not unnecessary recommendation that the authorities of the College should improve the present sanitary arrangements of the College. Only those who have been ill in College rooms, or those who have attended *patients* there, can realise how trying are the present arrangements.

ANTHRAX FROM SHAVING-BRUSHES.

THE Ministry of Health has called attention to the recent occurrence in this country of cases of anthrax, some of which have terminated fatally. Infection has once more been traced to shaving-brushes; in spite of the steps taken to prevent the distribution of Japanese brushes imported before the prohibition order took effect (i.e., Feb. 9th, 1920), there is reason to believe that large numbers of these brushes still remain in the hands of retailers. It is suggested that medical officers of health should communicate with all retail chemists and other dealers in shaving-brushes in their districts, and warn them of the danger of distributing any brushes of Japanese manufacture which they may have in stock. Should the retail dealer be unwilling to have the brushes destroyed, they should be securely wrapped up and returned to the wholesale dealer, together with an explanation. At the beginning of last year a method of partial disinfection of shaving-brushes before use was indicated[1] for the protection of the public, but a method stated to be more reliable is now recommended in a circular issued by the Ministry of Health. The brush should be: (a) thoroughly washed with soap and warm water containing a little washing soda and then allowed to stand for half an hour in warm water containing a little soda; (b) placed in a warm solution of formaldehyde (1 part of 40 per cent. formalin and 16 parts of water—a 2½ per cent. solution of formaldehyde) for half an hour; (c) allowed to dry. It is, however, pointed out that complete sterilisation of brushes is impracticable; the method mentioned above frees the exposed part of the hair from infection, but does not affect spores embedded in the handle of the brush. The following figures have been supplied by the Medical Inspector of Factories with regard to the results of various forms of treatment in 800 cases of cutaneous anthrax (excluding the erysipelatous form) in Great Britain:—

Treatment.	Cases.	Deaths.	Mortality per cent.
Serum only	200	8	4·0
Excision only	397	44	11·1
Excision and serum	174	25	14·4
No special treatment	29	14	48·3
Total	800	91	11·4

It is also stated that in general the best treatment for a case of anthrax is physiological rest of the part affected, combined with intravenous injection of anti-anthrax serum; and that there is always difficulty in estimating the efficacy of different methods of treatment of a malady such as anthrax, which is capable of undergoing spontaneous cure.

THE VENTILATION OF SUBMARINES.

THIS subject has been little discussed in the medical press, which makes more welcome the paper by Lieutenant-Colonel (Surgeon-Commander) R. Marantonio, of the Italian Navy, in *Annali di Medicina Navale* (1920, ii., 467). A small submarine, 100 ft. long and 10 ft. broad, displacing when fully submerged 200 tons, has a crew of 12, and takes down with her some 200 cubic feet of respirable air per man. This air is deteriorated not only by respiration, but by gases given off by the accumulators; as, however, not all parts of the boat are equally occupied, some parts retain a better atmosphere than others, and an equalising system of 4-inch trunks is installed to collect on the starboard side the used air by the help of a Sirocco fan, and discharge it, mixed, on the port side. This circulation does nothing to improve the air supplied, though the motion imparted makes it pleasant and cooling, but the air can, if preferred, be drawn through soda-lime granules, which remove carbonic acid and water vapour. Also, two steel cylinders of oxygen are carried as a reserve. When the boat comes to the surface, where its stay may be short, it is important at once to renew the air within it. That is not invariably easy, as the hatches are small and near the water, still it is managed by help of the Sirocco fan and the previously mentioned ventilation system. The valves on the trunks are set differently, air is sucked out of the ends of the boat, out of the latrine, out of the accumulators, and is driven overboard through an 8-inch trunk abaft the conning-tower, replacement occurring by drift through the hatches, or, if these are closed, through a second 8-inch trunk before the conning-tower. These trunks have their upper ends 8 ft. above the water and are closed by shutters and screws. In larger submarines (150 ft. long, 15 ft. wide, and displacing 474 tons submerged) ventilation is differently arranged and air purifiers are not used. The gases from the accumulators are the chief problem, and the exhaust air from the crew spaces is taken out through the accumulator chambers and pumped overboard to the nearer escape, of which there are two, one forward, one aft. When the oil-motors are running, the boat being on the surface, the required air is taken from the crew spaces, while the used air is discharged overboard, but there are always leakages, and to remove that air ("smoke") a ventilator is fitted at the after end of the engine-room. But this ventilator has to be at once closed if the boat begins to submerge, so that as she submerges the engine-room always wants a blow through. When submerging the openings are all firmly sealed and water is run into the ballast tanks, displacing the air there contained, air that has always a very unpleasant smell, and the barometric pressure increases to 31 in. From all which we learn there are unpleasantnesses in the submarine service as well as risks, and the call for equanimity is as clear as that for courage.

CANCER OF THE UTERUS IN YOUNG WOMEN.

ACCORDING to Dr. Gordon Gibson,[1] of the Long Island College Hospital, who records six cases in women aged from 25–28, cancer of the cervix under 30 is not so rare as is generally supposed. In 500 cases of cancer of the uterus recently reported by Petersen 23, or 4·8 per cent., occurred under 30. Dr. Gibson's percentage is higher, being 6 in 61 cases, or 9·9 per cent. It is noteworthy that 4 of his cases had married early—namely, at 19, 17, 16, and 17 respectively. Of the 5 who had borne children 4 developed the cancer comparatively soon after pregnancy—namely, 16 months, 3½ years, 4 years, and 5 months. In young women the growth, which is usually an epithelioma, is much more rapid than in older women, and it is only when it is seen in the first three months that a radical operation can be done. The extension is particularly rapid when the parametrium becomes involved and death takes place comparatively soon. In only three of Dr. Gibson's cases was the radical operation carried out, and in them the disease had given rise to symptoms for a comparatively short time—namely, three months, two months, and two months respectively. In the others, in whom the symptoms had been present from four to six months, only palliative measures, such as curetting and cauterisation, were possible, and all of them died shortly afterwards.

THE FORM OF MERCURY FOR INUNCTION.

IN the *British Journal of Dermatology and Syphilis* for December, 1920, there appears an interesting article on the absorption and elimination of mercury by Dr. Svend Lomholt, head of the Venereal Clinic of the Royal Danish Marine Hospital, Copenhagen. The author has made a careful analysis of the fæces and urine of patients under various forms of mercurial treatment, and daily charts of the rapidity of elimination of mercury have thus been obtained. Before dealing with the therapeutic conclusions arising from this work, Dr. Lomholt discusses the question whether mercury in the infected body acts directly upon the spirochætes, or indirectly by stimulating the bactericidal forces of the body. Eighteen examinations of blood from patients under full mercurial treatment or severely intoxicated with this metal have shown that the average content of mercury amounts only to 1–2 mg. per litre, and never exceeds 3 mg. The concentration is so feeble that it appears improbable that a direct bactericidal effect takes place. This conclusion is reinforced by experiments conducted in company with Dr. A. Kissmeyer, in which it was found that a colony of spirochætes grew well in horse serum containing 5–10 mg. of $HgCl_2$ per litre. Dr. Lomholt concludes with a review of the various methods of administration of mercury considered from the point of view of absorption and elimination. He is of opinion that the salicylate of mercury is not absolutely reliable, on the one hand, because its chemical composition makes it decomposable only with difficulty, and, on the other hand, because of its extremely rapid elimination. Metallic mercury has a very serious drawback in its slow and sometimes very irregular absorption, which may in some cases produce severe intoxication, and in other cases a feeble therapeutic effect. Treatment by inunctions possesses the advantage of being reliable, effective, and painless. To obtain a rapid saturation of the body, the author suggests that it may be of advantage to give at the beginning of the inunction treatment an injection of the soluble salt of mercury, or simply a dose of 0·5 g. of calomel per os. The daily dose of ointment to be used should vary from 3 to 5 g. according to the size, &c., of the patient. The injection of soluble compounds of mercury is not employed very much nowadays owing to the necessity of daily treatment, but it is specially indicated in idiosyncrasia mercurialis, where a tendency to "hydrargyria cutanea" prevents the use of inunctions.

LONDON PANEL PRACTICE.

THERE are just over 1½ million insured persons on the lists of insurance practitioners in London. Of these 4060, or 1 in 380, gave notice at the New Year that they were desirous of making a change of doctor. The names of 207 insured persons were removed from practitioners' lists at request of the latter. During the third quarter of last year just over 1 million prescriptions were given to insured persons, an average of 0·67 a head at a cost of 9·64*d.* each prescription, the expense being almost equally divided between the cost of ingredients and the fee for dispensing. One practitioner, whose prescriptions for the first quarter of the year averaged 1·11 (instead of 0·92) a head at a cost of 11·91*d.* (instead of 9·25*d.*) each prescription, was surcharged £2 4*s.* 8*d.* by the Insurance Committee on the ground that the drugs ordered were in excess of what was reasonably necessary for adequate treatment. Several of his patients received 25 or more mixtures each during this period. Only 47 insured persons applied to be allowed to make their own arrangements for medical benefit. Over 1,650,000 cards were issued for the new form of medical record which came into operation on Jan. 1st. The current issue of the *London Panel Committee Gazette* replies to certain general questions which have arisen as to the use of these cards. Practitioners are only required to record such clinical notes as they consider will be of use to them or to any practitioner who may subsequently have the care of an insured person. Where an independent record is kept of visits or attendances available for inspection by the regional medical officer it is allowed that after the first visit, or first three attendances, the total number of these may be entered weekly or monthly; the date of the first (or initial) certificate and that of the last (or final) certificate only require to be recorded.

THE CONCENTRATING ACTIVITY OF THE GALL-BLADDER.

IT has long been recognised that the gall-bladder must have a concentrating function, since bile from the gall-bladder is more concentrated or inspissated than that in the bile-ducts of the same animal. Previous experiment[1] has shown that the fluid which collects in bile-ducts artificially obstructed is an inspissated tarry bile when the ducts communicate with the gall-bladder, whereas in ducts unconnected with this viscus the fluid is thin and soon becomes free from pigments and bile salts. Mr. P. Rous and Mr. P. D. McMaster, of the Rockefeller Institute, taking advantage of the disposition of the bile-ducts in the dog, have sought to determine the rate of concentration. There are three hepatic ducts in the dog, which unite to form a common bile-duct, with the cystic duct opening high up into the central one. Through an opening near the lower end of this last a catheter was pushed into the neck of the gall-bladder, which was emptied and washed with salt solution, the duct being ligated after the catheter was withdrawn. The bile from the middle lobes of the liver thus had no escape save into the gall-bladder, while that from the lobes to either side still reached the common duct. From this it was collected into a rubber balloon placed in the peritoneal cavity, the abdominal cavity being then closed. A control experiment was made by substituting a similar balloon for the gall-bladder, which showed that the separated portions of bile differed little in their pigment content, which was taken as the index of concentration. After 24 hours the gall-bladder, still undistended, was regularly found to contain only one-sixth to one-tenth as much fluid as was shown on calculation to have reached it, but this, thick and dark, was six to ten times as concentrated in pigment as the control specimen in the rubber balloon. The results were the same when, without other variations in the experiment, the gall-bladder was filled to the normal distension with sterile bile of known character prior to withdrawal of the catheter. At the autopsy the branches of the hepatic duct always contained a thin bile like that in the balloon, a direct proof that the thick contents of the gall-bladder had not come as such from the liver. It is therefore evident that the gall-bladder can concentrate bile with very great rapidity, and this raises the question whether concentration of the bile in periods of intermittent or partial stasis may not be an important favouring element in the formation of gall-stones.

FRIEDMANN'S VACCINE.

THE controversy over the merits of Friedmann's vaccine appears to be raging as vehemently as ever in the German medical press and at medical meetings, the discussions at which are marked rather by heated partisanship than a judicial preference for truth. In the *Deutsche medizinische Wochenschrift* for Jan. 6th Professor W. Kruse, of Leipzig, complains bitterly of the open hostility with which his address on the subject of Friedmann's vaccine at the Medical Society of Berlin was greeted by his audience. He found it most galling, while voicing his conviction that this vaccine is of incalculable importance both as a prophylactic and as a remedy for tuberculosis in the early stages, to be constantly interrupted by cries of "Keep to the point." Professor J. Schwalbe's answer to this complaint in the same number of this journal is to the effect that when a provincial professor comes to Berlin to teach his colleagues wisdom he should not exasperate them by mouthing platitudes. The audience at the meeting of the Berlin Medical Society had come to hear what the director of the Hygienic Institute of the University of Leipzig had to tell them of his experimental investigations into the action of Friedmann's vaccine, and only after they had listened for some time to such truisms as "...... the germ of tuberculosis is evidently widely distributed and easily transmitted" had silent attention given place to interruptions. To outsiders unfamiliar with the petulant atmosphere in which the Friedmann controversy has been enveloped for several years, it must seem strange that after more than eight years' trial the remedy should still hold such an equivocal position in the medical world.

CARCINOMA OF THE PROSTATE.

Dr. H. C. Bumpus,[1] of Rochester, Minnesota, has made a study of 362 cases of carcinoma of the prostate observed at the Mayo clinic from 1914 to 1919 inclusive, with special reference to metastases. He considers that metastasis to the glands occurs more frequently than is demonstrable clinically—in his series it was found in only 37, or 10·2 per cent.—because of the inaccessibility of the glands first involved. He states that clinically and microscopically carcinoma of the prostate presents two fairly distinct types of enlargement. In the first and more malignant type the gland is so slightly enlarged, and gives rise to so few local symptoms, that the condition is often only recognised by the symptoms produced by metastasis. In the more common type of carcinomatous prostate urinary symptoms are more pronounced, and metastases occur later than in the first type. Owing to its lesser degree of malignancy this type is more amenable to radium-therapy. Dr. Bumpus estimates that one-third of the patients with carcinoma of the prostate have osseous metastases demonstrable by X rays, the most frequent sites being the pelvis, vertebræ, and femora. Pulmonary involvement is rare and occurs late in the disease, probably never without metastases elsewhere. In Dr. Bumpus's three patients in whom metastases were found in the lungs there was also pelvic and spinal involvement, and in two the ribs, and in one the femora were also affected. Spinal cord involvement which occurred in eight of his cases closely simulates primary spinal cord tumours, and is apt to occur when the prostate is only slightly enlarged, giving rise to pain simulating intracostal neuralgia or aneurysmal pains. Owing to the absence of urinary symptoms in a considerable proportion of all cases with metastases—11·5 per cent. in the present series—the possibility of carcinoma of the prostate should always be considered in men above middle age who complain of neuralgia and rheumatic pain. even in the absence of urinary symptoms.

MEDICAL PROVIDENT SCHEMES.

THE Sussex Provident Scheme for Hospital Benefits and Additional Medical Services, of which we were able to give the details in our issue of Jan. 15th, has not only gained the approval of all branches of the medical profession in the county of its origin, but is attracting a good deal of attention elsewhere. And rightly, for, given a comprehensive medical service debarring no one from obtaining every known means of diagnosis and treatment, it does not much matter whether it is paid for by a subscription or premium according to means, or by a tax or rate. The essential aim in either case is to organise a service which the patients can afford and which will at the same time afford fair remuneration to the doctors. The claims made on behalf of the Sussex Provident Scheme may be briefly summarised thus:—

1. That it calls for no capital expenditure and entails no expense either to the State, the rates, or the hospitals, nor does it ask for charitable contributions.

2. That it provides the hospitals with a new source of revenue which has great financial possibilities and may help to save the voluntary system.

3. That it does not materially interfere with the present work or the established routine of the hospital.

4. That, although not offering general practitioner attendance, it supplies its members with all those facilities which may be necessary for their efficient treatment in illness, and which are not provided under the National Health Insurance Acts.

5. That the ready access to these facilities must tend to the prevention and early arrest of disease, and so to an improvement in the standard of national health.

6. That it benefits the general practitioner by giving him wider facilities for diagnosis and treatment; by keeping in his hands many patients whom he would otherwise lose in hospital; and inasmuch as the members of the scheme can only obtain its benefits through their doctor, by giving him a position of greater influence and prestige.

7. That it benefits the consultant by providing remuneration for those members of the honorary staffs of hospitals who are willing to carry out its provisions with regard to consultations, whether personal or by correspondence, at the hospital; and by giving full fees for consultations at the patient's house, instead of the reduced fees which are now so often accepted. It is also obvious that these consultations are likely to be much more numerous when the general practitioner knows that they will entail no expense to his patient.

8. That it gives an opportunity of profiting by hospital treatment to people of many classes whose circumstances are really as necessitous as those of the manual worker, but who have hitherto felt themselves debarred from accepting charity, and have shrunk from the publicity of a hospital.

These ends are to be attained in the Sussex scheme by bringing in all the nine coöperating general and special hospitals on a uniform basis. Urgent cases will be admitted to hospitals as at present, other cases requiring operation or other hospital treatment will, after consultation, be admitted to hospital, or be placed upon the waiting list of the hospital until there is a vacant bed, but a member will not take precedence over more urgent cases, and the ordinary hospital routine will not be disturbed. In all the coöperating hospitals in which private beds are reserved at present for paying patients, members will be admitted to these beds if available, should they desire it, at a uniform reduction of 1 guinea a week from the usual price of the bed. The specific rules, which have been very carefully thought out for local needs, are as follows:—

1. No one will be accepted as a single member except an unmarried man or woman, or a widower or widow without children under the age of 16. The subscription for a single member will be £1 per annum

2. Married people without children, or a widower or widow with only one child under the age of 16 years, may only subscribe jointly at a rate of £1 10*s*. per annum for the two, although each shall be accounted a member.

3. Married people with a child or children under the age of 16, or a widower or widow with children under the age of 16 years, may only subscribe at a family rate of £2 per annum, which shall include the whole family, however large, except children over the age of 16, who must be accepted as single members, although each individual in the family shall be accounted a member. N.B.—These rates are subject to revision by the coöperating hospitals after due notice.

4. All candidates for membership must be approved by the "Committee of Reference" formed by the coöperating hospitals, *except in the case of those insured under the National Health* Insurance Acts, who will produce their medical card. In the event of the eligibility of any member being questioned, the matter will be submitted to the "Committee of Reference," whose decision shall be final.

5. Cards of membership, bearing the date, will be issued on the first day of each month to those who have become members during the preceding month, and the benefits will begin on the date of the card, and continue for one calendar year. These cards can be produced as evidence of membership.

6. At the end of one year from the date of issue of the membership card the benefits will cease unless the subscription has been renewed. Fourteen days grace will be given for renewal (during which no benefit will be available), but, after this, renewed membership will only be possible from the beginning of the next quarter.

7. When the number of members has reached the limit of the capacity of the coöperative hospitals the list will be closed.

8. When a member is leaving the county within the first six months of membership, and in consequence wishes to resign, one-half of the subscription will be repayable upon application.

Consultation fees are to be drawn from a pool formed by deducting 25 per cent. of the moneys allotted to each hospital, and it is obvious that the plan can be similarly applied to the conditions ruling in other areas. It should be carefully noted that the Sussex scheme does not include general practitioner services and is restricted to a maximum yearly income limit at present fixed at £260 for single members and £500 for a family. We publish this week for comparison a scheme for a London coöperative polyclinic drawn up by Mr. C. A. Parker, honorary secretary of the State Medical Service Association, which is of a still more inclusive nature and is intended also to cover the general practitioner service, and is not limited as regards maximum income. In each case the principle of assurance is the same, the fortunate by their annual contributions helping their less fortunate brethren, adhesion being *on* a voluntary basis.

THE ACTION OF SUPRARENAL TOXIC SERUM ON ATHEROMA.

THERE are two theories which hold the field with reference to the pathology of arterio-sclerosis, one which regards hypertension as the principal factor in the arterial lesions, the other which considers these lesions to be directly toxic in nature. Josué found that intravenous injections of adrenalin were followed by increase of arterial pressure, and subsequently produced atheromatous lesions in the arteries. Certain observers explain this experimental atheroma by the vasomotor, others by the toxic, action of the adrenalin, while others again, such as Lucien and Thévanot, hold that this substance acts simply through an atheromatogenous action independent of the two preceding. Observations by Etionne and Parisot, who, by submitting animals to intravenous injections of adrenalin and at the same time of vasodilatory substances, such as iodine and trinitrin, invariably obtained atheromatous lesions of the aorta, seem to indicate that increase of arterial pressure is not a necessary condition to the production of atheroma, and that this is, on the contrary, due to the atheromatogenous action of the adrenalin. Dr. Fabio Marabotto[1] has lately undertaken some new experiments on this question at the Istituto Maragliano at Genoa. Using a watery solution of suprarenal capsule he found it was possible to produce atheroma in rabbits when administered intravenously, but not when given by mouth or subcutaneously. This atheromatogenous action was constant and in direct proportion to the number of intravenous injections given to the animals, and it was always associated with a hypertensive action. By inoculating repeated small doses of emulsion of suprarenal tissue into rabbits Dr. Marabotto induced in their serum lytic properties towards suprarenal tissue and he found that alternate injections of suprarenal extract and of this suprarenal toxic serum, the latter subcutaneously, caused an infinitesimal degree of alteration in the aortic parietes *not in the least comparable with that produced by the* former alone. Similar results followed the administration by mouth of this toxic serum, but the arterial changes were rather more marked. There seems, therefore, a strong probability that such a serum, produced experimentally and having suprarenal toxic properties, may be of use in treating atheroma and arterio-sclerosis in the human subject. The whole question is full of interest; arterio-sclerosis is common, its effects far reaching, serious, and often fatal, its precise origin still undetermined, and any contribution to the solution of the problem, and especially with a view to establishing a scientific treatment, is worthy of the attention and consideration of pathologists.

---

HEALTH IN LONDON AND CALCUTTA.

THE vital statistics of the year 1920 for London, issued last week by the Registrar-General, are in striking contrast with those of the year 1919 for Calcutta, available in the report of the health officer which we summarise on p. 307. In London the general death-rate per 1000 living was 12·4, the lowest on record; the infant mortality-rate per 1000 births was 75, also the lowest on record. Dr. H. M. Crake gives the general death-rate for Calcutta as 42·2, the highest rate ever recorded in the city except that of the plague year 1900, and more than treble that of London. The rate varied widely in different parts of the city, reaching the appalling level of 81·1 in Kidderpur, and sinking to 15·3 in the Park-street area and actually to 5·8 in Fort William. There is evidently, as Dr. Crake remarks, nothing in the climate of Calcutta to necessitate this high general level of mortality, which is nearly 50 per cent. higher in females than in males. As regards racial incidence, the death-rate was 45·2 for Hindus, 37·9 for Mohammedans, and 27·4 for non-Asiatics. Cholera, small-pox, and influenza were all present during the year in acutely epidemic form. Plague also was on the increase, enteric fever was more prevalent than in any of the five preceding years, tuberculosis was slightly more fatal, and there was a mysterious outbreak of epidemic dropsy in the latter part of the year. Dr. Crake deals with some of the known causes of these figures—the purdah system depriving women of fresh air and constantly exposing them to insanitary environment, the many potential plague centres, the contamination of water tanks by ceremonial ablution, the movements of pilgrims, the presence of typhoid carriers, the waning protection of vaccination. It certainly seems time that some of the enterprise and effective sanitary administration which have made of London one of the healthiest cities of the world should now be devoted to a concerted campaign against disease in the old capital of the Indian Empire. There is abundant outlet there for the new applications of social medicine, and the new School of Tropical Medicine and Hygiene will be fully opened in Calcutta next month.

THE opening letter in our correspondence columns reiterates the plea, which we have made more than once, for harmonious coöperation in the attack upon venereal diseases. A review of Sir Archdall Reid's book on p. 279 should be read in this connexion.

A SUGGESTED
LONDON COÖPERATIVE POLYCLINIC.

BY CHARLES A. PARKER, F.R.C.S. EDIN.

IN view of the recognised necessity of "team" work amongst the medical profession, and of the strong recommendations of the Dawson Report for a health service "available to all citizens," I suggest that a group or team of medical practitioners should be formed to provide a complete medical service, with a well-equipped health centre, primarily for that large section of the community whose incomes are above the limit of the National Insurance Act, but which nevertheless is unable to provide for itself the costly methods of diagnosis and treatment of the present time. It is especially unable to afford the fees of private nursing homes, and has consequently to seek admission to the voluntary hospitals, thus draining their resources and adding to their long waiting lists.

This section of the community, many of whose members have small fixed incomes, are especially hit by the present high cost of living, and are finding the difficulties consequent upon illness even greater than they were before the war. The provision of such a medical service as that now contemplated is, therefore, more than ever necessary.

The scheme here presented is based upon the principles of insurance, whereby the fortunate by their annual contributions help their less fortunate brethren. This principle is sound, and has been applied with marked success to life, accident, sickness, fire, and burglary, and, indeed, to almost every conceivable risk, and there is every reason to believe that it could be applied with equal success to the provision of medical services. Whilst the scheme is primarily intended for those whose incomes exclude them from the benefits of the National Health Insurance Act, it is nevertheless recognised that there is at present no organised service of consultants and specialists available to nationally insured persons. It is therefore proposed to throw such services open to them at a modified fee. The outlines of the scheme here follow.

Objects.

(1) To provide a complete medical service, including general practitioners, consultants, and specialists of all sorts, for members of the middle classes, not provided for by the National Health Insurance Act, on the principle of voluntary insurance.

(2) To provide a health centre with all necessary consulting-rooms and special departments.

(3) To provide a private hospital, or other hospital accommodation, for its members.

(4) To provide consultative and specialist services, and as far as may be possible hospital accommodation, for those insured under the National Health Insurance Act.

Membership.

Membership shall be limited to persons having incomes between £250 and £1500 or £2000 a year (together with their families), and to those residing within the London postal area. Insured persons (N.H.I. Act) shall be eligible for the consultative, specialist, and hospital portions of the service in consultation with, or accompanied by a written report from, their general practitioners.

Benefits.

The annual subscription shall entitle members to the following benefits: (1) The services of a general practitioner; (2) medical assistance at confinements; (3) the services, when necessary, consultative and operative, of the consultative and specialist staff—individually or collectively; (4) consultations with consultants and specialists other than members of the staff at specially arranged fees; (5) hospital treatment when necessary, provided there be vacant beds; (6) free choice of doctors belonging to the Service.

N.B.—Under special circumstance members shall be permitted to subscribe for the consultative, specialist, and hospital portions of the service only, but they shall only be eligible for such portions in consultation with, or accompanied by a written report from, their general practitioners. This shall also apply, as stated above, to insured persons (N.H.I. Act).

Subscriptions.

Annual subscriptions shall be based on incomes and shall be in accordance with one of the tables attached hereto, or with some modification thereof. The annual subscription for restricted benefits shall be half the subscription for full benefits + 10 per cent., the minimum subscription being in all cases one guinea (£1 1*s.*).

N.B.—Married members must insure *all* their dependents. Drugs and surgical appliances are *not* covered by the subscriptions.

The Medical Staff.

The medical staff shall include: general practitioners, consulting surgeons and physicians, specialists in all branches of medicine and surgery and allied sciences, and consulting dentists—for advice only.

General practitioners.—General practitioners shall form an important part of the organisation and shall in every way be on an equality with the consultative staff. They shall be entitled to the use of the health centre and to its equipment when necessary to them in their work. They shall work in close coöperation with the members of the consultative staff. All general practitioners shall be at liberty to join the staff of the polyclinic, and shall hold office subject to the rules to be drawn up by the committee of management.

Consultants and specialists.—All members of the consultative staff shall be appointed by the committee of management upon the recommendations of a specially appointed committee of selection. They shall (*a*) hold office subject to the rules drawn up by the committee of management; (*b*) attend the health centre on specified days at specified hours for the purpose of seeing patients; (*c*) work in close coöperation with the general practitioners; and (*d*) visit patients in their homes at the request of any other member of the staff, general practitioner or consultant.

Methods of Remuneration.

General practitioners shall be paid at the rate of £1 2*s.* per head of potential patients on their lists. They shall be paid 5 guineas for each confinement. The consultative staff shall be paid in the first instance on a time basis, but later on a definite fee per session will probably be the better plan.

The Private Hospital.

Members of the polyclinic shall be given the first call on all beds of the hospital. They shall be admitted free to the wards of the hospital; moderate fees shall be charged for the use of a private room. When there are vacant beds *non-members may be admitted, preference being given to* patients of the members of the staff. Non-members shall be charged, say, £5 5*s.* a week for a bed in a ward and £8 8*s.* for a private room.

Profits.

All profits shall be applied to one of the following objects: (1) increasing and improving the equipment of the health centre; (2) enlarging or improving the private hospital; (3) reducing the premiums for membership of the polyclinic.

Management.

The management shall be vested in a committee of 12 persons, eight of whom shall be members of the medical staff and four subscribing members of the polyclinic. There shall be a president (lay or medical), who shall be nominated by the Minister of Health, the President of the Royal College of Physicians of London, or the President of the Royal College of Surgeons of England.

The president shall be ex officio chairman of the committee of management. The eight medical members shall be elected by the members of the medical staff, all of whom shall have the right to vote. The four lay members shall be nominated by the president from amongst the members of the polyclinic (or shall be elected at an annual general meeting of the subscribers).

There shall be an honorary treasurer whose duties shall be defined by the committee. The accounts shall be audited by professional auditors appointed by the committee. There shall be a salaried secretary-superintendent, who shall be responsible for the organisation and management of the polyclinic and the private hospital.

Finance.

A small company, registered as a non-profit-earning company, shall be formed for the purpose of acquiring by rent or purchase and of equipping a health centre and private hospital. The necessary capital shall bear a fixed rate of interest, say 6 per cent. A sinking fund shall be established for the purpose of redeeming the capital as soon as possible.

The company shall sublet the health centre and private hospital to the London Coöperative Polyclinic at a rental equivalent to its out-goings, together with 6 per cent. on the capital invested until such is redeemed.

Initial Steps.

In order to carry this scheme into effect it would be necessary to:—

(1) Form a temporary organising committee to approve or amend these suggestions, to get the necessary legal advice, and to get further actuarial advice as to which table of premiums is likely to prove most attractive to the public.

(2) Invite general practitioners to join the staff and to invite applications for the consultative staff of the health centre.

(3) Make the scheme known to the public and open a list of membership.

(4) Open a subscription list for debenture shares at 6 per cent. in the London Polyclinic, Ltd., with the object of providing and equipping the health centre and private hospital and of covering the outgoings for the first two years.

It would not be necessary to wait until the capital had been raised and the health centre and hospital had been equipped, for, in the first instance, it would be possible to arrange with the consultative staff to see patients at their own homes or to obtain the use of one or two rooms as a nucleus of the health centre. It would also be possible to arrange with bacteriologists and radiographers to carry out the necessary work of the polyclinic at their own laboratories. As regards hospital accommodation arrangements could be made with general and special voluntary hospitals and with private nursing homes to take in cases for the polyclinic at fixed rates. Voluntary hospitals could be given a donation of £4 per week per patient admitted, which would be a help towards their funds.

If this scheme were successfully launched in London it could easily be extended to the provinces, and finally to the whole country. It would have the great advantage of keeping the control and management in the hands of medical men and their patients, and it might render an extended system of *compulsory* insurance, now in the air, unnecessary.

Premium and Expenditure Tables.

Explanatory Note.—The last Census returns show that of every 1000 of the adult population—i.e., over 20 years of age—695·5 are married, and that each married couple has an average of 2·2 children. For the purposes of these tables the round figures of 700 married and 300 single are taken. The proportion of 1000 breadwinners or income-owners having the incomes specified are taken from income-tax returns. The necessary premiums are based upon a unit of 1000 breadwinners and 1000 nationally insured persons, but with 5000 subscribing breadwinners and 2000 insured persons the premiums could be reduced by 25 per cent.

TABLE I.—*Premiums per Head of Insured Persons.*

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Sensitised Rabbit Serum for Hæmorrhage.

Mons. H. Dufour has issued the interesting results of researches carried out in his laboratory at the Hôpital Broussais in Paris on the use of an antihæmorrhagic serum discovered by him and known as anthema. Mons. Dufour had previously observed[1] that horse serum used as a hæmostatic drug has a marked effect only when it happens to cause anaphylaxis. Anthema is rabbit serum which has been sensitised by the anaphylactic effects of repeated intravenous injections of horse serum. Mons. Dufour, having discovered that rabbit serum prepared in this way causes hypercoagulability of the blood when injected into guinea-pigs, reported this fact to the Académie de Médecine, and advocated the use of anthema serum in cases of hæmorrhage. In a recent article[2] he records most satisfactory results obtained in 20 cases of various kinds of hæmorrhage (epistaxis, hæmoptysis, hæmatemesis, hæmophilia, and intestinal hæmorrhage in typhoid fever). The cases were observed by Mons. Dufour himself and MM. A. Schwartz, G. Caussade, and P. Raymond. The dose consisted of a hypodermic injection of 10 to 20 c.cm. of anthema, which was repeated in certain instances.

Unsuccessful Action against a Medical Practitioner.

A case which has aroused great interest amongst medical practitioners has lately been heard at Nimes, where a doctor was unsuccessfully prosecuted for homicide through imprudence. The charge was against Dr. F. Mazel, who had been called by a Major Arnaud to attend to his two daughters, both of whom died, one in December, 1915, and the other in January, 1916, and Fr.200,000 damages were claimed. The accusation against him was that he changed without sufficient reason the treatment prescribed by the late Professor J. Grasset, that he prescribed subcutaneous injections of strychnine in too large doses, that he procured a nurse who proved incapable, that he continued the course of injections in spite of the formation of secondary abscesses, and that he performed useless lumbar punctures. A Paris physician, Dr. F. Dervieux, who was appointed as medical expert, was of opinion that it was not from typhoid fever that the patients had died, but from septicæmia following septic injections; as he thought that the nurse who gave them had not been sufficiently watched by Dr. Mazel he concluded the responsibility of the accused was undoubted. However, rebutting evidence was given by other doctors in the course of the trial. The verdict of the case, awaited with much concern by medical practitioners, was in Dr. Mazel's favour, and has been received with general approval.

URBAN VITAL STATISTICS.

(Week ended Jan. 29th, 1921.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate population estimated at 18½ million persons, the annual rate of mortality, which had been 13·9, 12·8, and 13·3 in the three preceding weeks, fell to 12·3 per 1000. In London, with a population of 4½ million persons, the death-rate was 11·6, or 1·3 per 1000 below that recorded in the previous week, while among the remaining towns the rates ranged from 5·9 in Bootle, 6·6 in Reading, and 6·9 in Ilford and in Cambridge, to 19·7 in Middlesbrough, 19·8 in Sunderland, and 21·3 in Barnsley. The principal epidemic diseases caused 250 deaths, which corresponded to an annual rate of 0·7 per 1000, and comprised 90 from infantile diarrhœa, 80 from diphtheria, 33 from whooping-cough, 23 from measles, 22 from scarlet fever, and 2 from enteric fever. Measles caused a death-rate of 1·2 in Middlesbrough, whooping-cough of 1·6 in Willesden, and diphtheria of 2·6 in Ipswich and 2·9 in Barnsley. There were 4171 cases of scarlet fever, 2682 of diphtheria, and 1 of small-pox under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 4350, 2618, and 1 respectively at the end of the previous week. The causes of 25 of the 4360 deaths in the 96 towns were uncertified, of which 5 were registered in Birmingham, and 3 each in South Shields and Gateshead.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 18·4, 15·9, and 15·8 in the three preceding weeks, rose to 16·3 per 1000. The 323 deaths in Glasgow corresponded to an annual rate of 15·3 per 1000, and included 10 from whooping-cough, 8 from infantile diarrhœa, 4 from diphtheria, 2 from small-pox, and 1 each from measles and scarlet fever. The 160 deaths in Edinburgh were equal to a rate of 18·7 per 1000, and included 4 from measles, 3 from infantile diarrhœa, and 1 each from whooping-cough and diphtheria.

Irish Towns.—The 128 deaths in Dublin corresponded to an annual rate of 15·8, or 0·8 per 1000 below that recorded in the previous week, and included 4 from infantile diarrhœa, 2 from whooping-cough, and 1 from diphtheria. The 136 deaths in Belfast were equal to a rate of 16·9 per 1000, and included 6 from whooping-cough, 3 from infantile diarrhœa, and 1 each from enteric fever, scarlet fever, and diphtheria.

"Audi alteram partem."

PROPHYLAXIS IN VENEREAL DISEASE.

To the Editor of THE LANCET.

SIR,—The dispute which is being waged on the subject of prophylaxis in venereal disease has long ago lost the characteristics of a scientific discussion and is rapidly acquiring those of a family quarrel. What is more distressing still is the fact that this quarrel has spread beyond the confines of the medical into the lay press, so that the noise and clamour of it are plainly heard by the man in the street. Small wonder that the latter has shrugged his shoulders and lost his confidence in those to whom he is entitled to look for leadership and advice.

Has not the time come for emphasising points of agreement rather than those of dispute? Two societies exist for the purpose of combating venereal disease; on their lists of membership appear names that command respect and consideration for the opinions that each society has advanced. No one who has seen the excellent work achieved by the N.C.C.V.D. can consider it an effete body that has sacrificed every practical measure to a sentimental fetish. No one who has read the list of membership of the S.P.V.D. can suppose for one moment that such eminent men would deliberately support a policy that is calculated to undermine the moral welfare of the community. In spite of the noise and dust raised by various extremists it is certain that there exists a considerable sphere of activity common to both societies. It is only over the question of prophylaxis that the split has arisen. The S.P.V.D. is convinced that the packet system has been instrumental in materially reducing the incidence of venereal disease in the Services, and believes that its adoption by the civil community would be equally productive of good. The N.C.C.V.D., on the other hand, is dissatisfied with the results of prophylaxis in the Services, and does not in any case believe that the adoption of the packet would be effective when applied to the civil community. Each of the societies has put forward statistics upon which the other has cast doubts, and each has arrived at conclusions which are endorsed by experienced authorities. Where does the truth lie? It is difficult, or impossible, at the moment to say. Statistics can be found to prove or disprove most of our prejudices, and our attitude towards the question of "packets for the people" must for the present be based on personal opinion rather than established fact. The centre of truth, like the centre of gravity, lies somewhere between the two extremes. It is possible that the N.C.C.V.D. has underrated the importance of prophylaxis in the campaign against venereal disease. It is equally possible that the S.P.V.D. in its enthusiasm for a neglected remedy has tended to regard it as the "single measure that will cure our ills."

There is work for all in the campaign against venereal disease. The N.C.C.V.D. is doing yeoman service in its educational campaign and in its agitation for the provision of free and adequate treatment for venereal disease throughout the world. The S.P.V.D. is convinced of the success of prophylaxis in the army and believes that its extension to the civil population will be equally productive of good; its action is the logical outcome of these views. Let each of the societies work along the line it has chosen, but let it be recognised that until further facts are forthcoming it is upon personal opinion rather than upon verified fact that its conclusions must rest.

Lastly, may I put forward a suggestion that has already been made. Is it asking too much that members of the two societies should arrange to meet? Surely it is better that differences of opinion should be amicably discussed in a meeting of medical men rather than be made the subject of a bitter and somewhat tedious correspondence in the press. I believe that if such a meeting could be arranged a vast amount of common ground would be found to exist between the two societies, and that a satisfactory working agreement could be arrived at on this thorny subject of prophylaxis. I am, Sir, yours faithfully,

Harley-street, W., Jan. 26th, 1921. KENNETH M. WALKER.

PART-TIME OR WHOLE-TIME FOR THE M.O.H. AND S.M.O.

To the Editor of THE LANCET.

SIR,—While agreeing with Dr. A. M. Barford's letter on this subject in THE LANCET of last week in regard to the merits and claims of the general practitioner, I beg permission to re-state the case categorically and more accurately. The question of relative professional attainment does not arise, though it might be strongly argued either way, and, unfortunately, the very lowest standard in this is compatible with "success" in general practice.

The arguments against "whole-time" service are as follows:—

1. It divorces a man from professional work, occupying him with routine.
2. Even of this there is not a sufficiency to keep him busy.
3. The consequent idleness attracts "undesirables" in spite of the low, but in the circumstances adequate, remuneration.

Against "part-time" work *by a general practitioner* may be urged:—

1. That urgent private calls are apt to conflict with official duties.
2. That a greater temptation exists to "scamp" work on account of impatience, fatigue, &c.
3. That the public appointment is apt to be regarded as a makeshift or stepping-stone to the more lucrative practice.
4. That the double duties leave no time for study and research.

Dr. Barford's suggestion that general practice demands or even encourages professional knowledge, and that its exactions in this respect are dreaded is grotesque, and it is to be hoped that his inaccuracy expends itself in his letters. Yet there is some truth also in his remarks. Does "whole-time" school medical service isolate from professional experience? Yes; but the fault lies with the general profession, which claims the treatment of all but minor ailments. It ought not to make this (its own arrangement) a ground of professional disparagement. Not only do the precautions to exclude from treatment all non-necessitous cases hinder us, but the rest of the "routine" is prescribed by Dr. Barford's own department.

He has, in fact, confused two distinct questions—that of "whole-time" *v.* "half-time" service, and that of the value and rival claims upon the service of "statistical research" and of "treatment." Of course, it is quite obvious that both classes of S.M.O.'s do precisely the same work.

I am, Sir, yours faithfully,
I. D. SUTTIE, M.B., Ch.B., F.R.F.P. & S. Glasg.,
Glasgow, Jan. 31st, 1921. Assistant S.M.O., Glasgow.

To the Editor of THE LANCET.

SIR,—As an assistant S.M.O. allow me to make a very emphatic protest against Dr. A. M. Barford's most unjust, insulting, and sweeping denunciation of whole-time M.O.'s, directed, as it was, with particular virulence, towards assistant S.M.O.'s. If we are to believe your correspondent, assistant S.M.O.'s, as a class, are good-for-nothing slackers, unworthy of their hire. For he says:—

> "It appears that the whole-time appointments are often sought after by members of the profession who shrink from the responsibilities and competition of general and special medical and surgical practice because of its hard work and the ever-increasing knowledge and skill required in order to be efficient. ...... It appears that the young medico of to-day desires to obtain a job with as little work as possible. .... The whole time M.O. cannot be said to be a man of the most enterprising and energetic ideals in the practice of his profession."

Now, if Dr. Barford has really met with such despicable characters I cannot see that there is any justification for putting us all in the same class. One butterfly does not make a summer, or one black sheep a black flock. To say that because a man does not select general practice for his life's work he is an unambitious slacker, or, in his own words, "cannot be a man of the most enterprising and energetic ideals" is simply foolish and not true, or we must class the leading lights of the whole-time service as such. It may be argued that these men are exceptions, which I readily admit, but at the same time I submit that the majority of assistant S.M.O.'s aim at higher posts; as Dr. Barford admits himself by describing us as "birds of passage," so that we cannot be called lacking in ambition and enterprise, as it is well known that the higher posts mean ever-increasing work and responsibility without a corresponding increase in salary. As to the time-table he has so kindly made out for us in his endeavour to prove that we cannot do a decent day's work, he omits to allow any time for getting to our destination or getting back, and very generously allows half an hour longer for lunch than is the custom, and also starts half an hour later than necessary at each session. In the West Riding of Yorkshire, at least, it is quite possible to begin work at 9.30 A.M. and 1.30 P.M. sharp without in the least interfering with the "call over" or religious instruction. To keep to this time-table it is necessary to leave home about 8.30 A.M. for most of the schools, and on an average one gets back about 5 P.M., which represents a good eight-hour day, not allowing for any clerical work done at home. If the general practitioner was only to reckon the actual time spent in examining patients and giving advice I venture to say his time-table would not look very imposing in most cases. As to the value of our work, I will refer you to the Annual Report of the chief M.O. of the Board of Education, wherein it will be seen that considerable importance is attached thereto by those best qualified to judge. Dr. Barford's letter brings us no nearer the solution of part-time or whole-time service.—I am, Sir, yours faithfully,

G. W. FLEMING, L.R.C.P. & S. Edin.,
L.R.F.P. & S. Glasg.,
Feb. 1st, 1921. Assistant S.M.O., West Riding.

To the Editor of THE LANCET.

SIR,—Would Dr. A. M. Barford, whose communication under this heading was published in THE LANCET last week, be kind enough to give a list of the delectable public health appointments to which he refers? I am certain there must be many assistant M.O.H.'s who would be very thankful to have the information; certainly there would be no lack of applicants when such posts were advertised. A four-hours' day for only five days a week, and that for only 38 weeks in the year, sounds so wildly improbable to those who have had experience of the many disadvantages and discouragements associated with junior posts in the public health service that it is difficult to believe Dr. Barford has not been indulging in phantasy.

I am, Sir, yours faithfully,
Cambridge, Jan. 31st, 1921. J. H. GELLATLY.

To the Editor of THE LANCET.

SIR,—Dr. A. M. Barford, whose letter under this heading appeared in your issue of Jan. 29th, obviously writes on a matter of which he has only partial knowledge, acquired, one would guess, within very narrow limits. Passing over his severely unkind and untrue description of the applicants for whole-time public appointments, I am led to wonder where Dr. Barford gained his knowledge of school medical work. He starts away with a fundamental error (which I was beginning to hope even laymen had forgotten by now)—viz., that the work of the school medical service is routine inspection.

> "The school *medical service is* a national institution and its task is of vital interest, not merely to diminish the ordinary wastage of infant life, but also to make and keep the rising generation sound in body and mind."

I find, too, that my experience is directly at variance with Dr. Barford's statements when he says that the assistant S.M.O.'s are a string of "birds of passage." It is quite exceptional here and in many other areas of which I have an intimate knowledge for these officers to be frequently changed. His contention that they cannot do a reasonable amount of work in the year is like other of his statements—not universally true. In Sheffield, and in many other places I know quite well, clinics are held every Saturday morning, and assistant M.O.'s are not always unemployed when the schools are closed, as he apparently would have us believe. When he says that "much of this work is very shoddily done," I must avoid the obvious retort, and get what comfort I can from the reflection that he may be as wrong in this as I suspect him to be. Pessimist he certainly is, and his prediction of the early extinction of the whole-time officer therefore should fail to act as a deterrent to those whose inclinations would lead them to enter other ranks than those of the noble army of general practitioners.

I am, Sir, yours faithfully,
Sheffield, Feb. 1st, 1921. T. CHETWOOD.

AN ATTACK ON LUNACY ADMINISTRATION.

To the Editor of THE LANCET.

SIR,—The article on Lunacy Reform in the *Medical Press and Circular* to which Dr. J. B. Tighe drew attention in your last week's issue appears to be only a part of an organised attack on lunacy administration. The statements quoted by Dr. Tighe must appear to everyone really acquainted with public mental hospitals as monstrous exaggerations and perversions. They appear to be the outcome of prejudice rather than of sane and sober desire for the welfare of the insane. They are sufficiently contradicted, if contradiction were necessary, by the evidence of the Mental After-Care Association, whose experience, in recent years of some thousands of recovered cases, is that these almost invariably express the warmest gratitude for the good and kind treatment they have received from the officers and attendants of these institutions throughout the country, and whose physical condition is a good evidence of the care given to their nutrition and general health.—I am, Sir, yours faithfully,

Hampstead, N.W., Jan. 31st, 1921. HENRY RAYNER.

PATCHWORK ANATOMY.

To the Editor of THE LANCET.

SIR,—In an annotation with this title in THE LANCET of Dec. 11th, 1920 (p. 1212), you do me the honor of discussing at length my book on the "Fundamentals of Human Anatomy." Let me here express my appreciation of the generous tone of the article, more particularly as in the United States we are apt to consider the Britisher ultra-conservative, even a bit antagonistic to new ideas. However, as the professional viewpoint gives mainly one side of the story I trust your readers will be interested in the following defence from the practitioner's point of view.

You consider my effort "an honest attempt to achieve the impossible," and in my turn I cannot conceive of a more felicitous phrase to express how the sympathetic practitioner feels toward the effort of the specialist in anatomy. The specialist maintains correctly that every point in anatomy has either present or potential practical value, and tends to attempt to teach every one—the impossible! Almost all practitioners agree that this is so.[1] My book starts with the assumption that for any individual to know everything about anatomy is an impossibility, and therefore attempts to select such major points as are of everyday importance to practitioners in any or all the subdivisions of our medical science from such as are less frequently required or are of real interest only to various special groups. And on how well or how poorly this selection has been made depends, in final analysis, the success or failure of this effort. This book was evolved to fill what I considered an unsupplied and yet fundamental need, with no idea of exclusion, for surely every posted man must recognise the necessity for anatomies from all special points of view, as well as for reference encyclopedias and complete atlases. The other progressive feature worthy of special note is that the concise descriptions of gross anatomy are illuminated and vitalised by the sidelights from histology, embryology, physiology, pathology, and the practice of medicine and surgery.

---

[1] See Proceedings American Congress on Medical Education, March, 1920, abstracted Jour. Amer. Med. Assn., vol. lxxiv., No. 12, pp. 824–825; and the Proceedings of the Fourth German Congress of Medical Faculties, January, 1920, summarised Jour. Amer. Med. Assn., vol. lxxv., No. 14, p. 953; and the review in the British Journal of Anatomy, vol. liv., July, 1920, p. 332.

To sum up, the grave shortcomings in the anatomic knowledge of practitioners are widely conceded. The professional anatomist blames it on the clinician, the clinician on the professional anatomist, and latterly the pendulum throughout the world has at least started to swing toward "anatomy in its relation to practice." In conclusion, allow me to quote the final sentence of my preface: "If this volume tends in any degree, directly or indirectly, to bring the teacher and student of anatomy into closer sympathy it will have fulfilled its mission." I am, yours very truly,

St. Louis, Mo., U.S.A., Jan. 10th, 1921. MARSH PITZMAN.

*** We have much pleasure in publishing Dr. Pitzman's views and their sound reasons.—ED. L.

THE INDICATIONS FOR REMOVAL OF TONSILS.

To the Editor of THE LANCET.

SIR,—The article by Mr. M. Vlasto which appears in your issue of Jan. 22nd contains several points which call for comment. The first of these is the statement that tonsillotomy secures drainage for the deeper crypts of the tonsil. Surely the scar-tissue, which is formed as the result of this or any other operation, must bring about just the reverse condition, and is the great argument against this particular operation in any case where one suspects that the "deeper crypts" are involved. Secondly, I do not consider that guillotine enucleation can be satisfactorily performed under short anæsthetics such as ethyl chloride—unless one is satisfied with a "scramble operation." I submit than an adequate general anæsthesia is necessary in all these cases, whether child or adult, if anything like routine success is to attend the efforts of the surgeon. In order to decide if tonsils can be successfully enucleated by the guillotine method it is best to wait till the patient is anæsthetised, and then see whether the tonsil can be dislocated from the pharyngeal wall, and pushed completely through the ring of the guillotine. The instruments for both varieties of technique should be sterilised and at hand, otherwise one is bound to encounter the futile situation where the anæsthetic has been given for a rapid enucleation with guillotine and closer investigation proves that dissection is necessary. It is also vitally important, in either case, that the surgeon should have time to secure any obvious bleeding point and satisfy himself that all bleeding has been controlled *before the case leaves the theatre.*

The writer hardly refers to this possible complication, which cannot be provided for by one of the short anæsthetics: use of the latter, therefore, should not be considered an advantage of enucleation by guillotine. He states that "less traumatism of the tonsillar bed" is produced by the guillotine method than by dissection, and that of two tonsils, one enucleated with the guillotine and the other by dissection, the former will have a capsule "smooth and white," in comparison with the "rougher surface" and "ruddy tinge" of the latter. I maintain that in both these cases the difference is due not to the instrument used, but to (*a*) the tonsil itself and its past history, and (*b*) the skill of the surgeon; and that whereas one of the "small fibroid septic tonsils" enucleated by either method will always present in a greater or less degree "the ruddy tinge of its muscular bed," another tonsil which has not undergone those repeated attacks of inflammation can be removed, with its capsule just as "white and smooth," by means of dissection as by enucleation with the guillotine. *Assuming* the skill of the surgeon to be beyond question, the former type will always be attended with more "after-pain" than the latter, whatever instrument is used. Enucleation with the guillotine is, in my experience, no more "messy" than dissection: nor do I find the "shape" of the adult tonsil to present any disadvantage to the use of the guillotine where this instrument is not contra-indicated by adhesions of capsule, &c.

In conclusion, I feel that throughout the article the writer has not laid sufficient stress on these facts: first, that consideration of the tonsil itself must decide which instrument can best be employed; secondly, that a longer anæsthesia than that produced by ethyl chloride, &c., is essential to success in this operation.

I am, Sir, yours faithfully,

Worcester, Jan. 31st, 1921. J. B. CAVENAGH.

To the Editor of THE LANCET.

SIR,—The perusal of the interesting and helpful papers by Mr. W. Morris and Mr. M. Vlasto in THE LANCET of Jan. 22nd on the removal of tonsils induces me to suggest to your readers the combination of methods for extraction by means of the guillotine which I have, after trying, found most effective in my hands.

Standing on the left side of the patient if he is recumbent, or sitting in front of him if he is in a chair, I commence on the left tonsil (before it has been made slippery by blood) and use a Morell Mackenzie guillotine in my right hand. While steadying counter-pressure is exercised on the left cheek by the anæsthetist I slip the ring over the tonsil and draw this forward on to the tuberosity of the lower jaw; then I exercise pressure outwards, against the jaw, so that the tonsil is made to "squash" through the ring, becoming everted in the process. Lastly, the blade is pushed home and is almost invariably found to have cut out the tonsil completely with the capsule on its deeper surface, and a narrow ring of mucous membrane, like a circumcised prepuce, round its margin. I then take up Ballenger's guillotine in my right hand, push the extremity of the ring behind the right tonsil, which I force from before backwards through the ring, by means of my *left forefinger*, press the tip of the guillotine forwards by levering the handle of the instrument on to the left cheek (which is pressed still more to the right by the anæsthetist) and cut out the tonsil quite as completely as on the left side, but with rather *more* mucous membrane. (Instead of Ballenger's, Mackenzie's guillotine, reversed, can be used.) With my left forefinger I clear the adenoids from the lateral walls of the naso-pharynx so as to press them towards the middle line. Then with Laforce's adenoid box-curette I remove the mass, any remnants being scraped away with Golding-Bird's curette. Lastly, I palpate the posterior extremities of the inferior turbinals, and if I find them enlarged I remove the excess by means of Prince's forceps.

These may seem trumpery details, but it has taken me some time to decide on this mode of removing both tonsils *with my right hand*, being a combination of Sluder's and Whillis's methods.

I am, Sir, yours faithfully,

Harley-street, Feb. 1st, 1921. JAMES DUNDAS-GRANT.

THE DIET OF WELL-TO-DO CHILDREN.

To the Editor of THE LANCET.

SIR,—If you bend the sapling and keep it bent you cannot avoid an angular oak tree. If you overload the juvenile intestine you must expect to find kinks and bands in the adult colon. That we should overload those poor little intestines at all is bad enough, but that we should overload them with the wrong material is infinitely worse.

Intestinal stasis is a deficiency disease. The complete absence of vitamines *from children's food*, which is secured by boiling milk against the bacillus, is the beginning as well as the *head and front of the offending.* If vitamines were supplied instead of being suppressed there would be no overloading, for surfeit would then be followed by a wholly beneficent diarrhœa. The surfeit of boiled milk and other devitalised foods gives rise to intestinal fatigue and stagnation; hence the stasis with its multiple and incalculable consequences. It is surely time that the broad human common-sense irradiated by Dr. Des Vœux's letter in your issue of last week replaced the bacillophobia and pseudo-scientific shibboleths of drug therapeutics which still pervade and degrade the teachings of the schools. We have attained to the point of admitting that the milk of the human mother is better than that of the pasteurised cow. Can we not follow that line of reasoning to its logical, adolescent, and adult conclusion by calling in and cultivating our vitaminous friends to defy our microbic enemies? If we were less given over to antiseptics we should be much more aseptic.

I am, Sir, yours faithfully,
Harley-street, W., Jan. 30th, 1921. LEONARD WILLIAMS.

REFERRED PAIN.

To the Editor of THE LANCET.

SIR,—I have just read the leading article in your issue of Jan. 22nd on the question of "referred pain," and am *surprised at the conclusion that* "reflex, reflected, or, better still, deflected pain, is far from being the common accompaniment of abdominal diseases it is uncritically taken to be," and still more surprised at the grounds for this conclusion—namely, that Dr. A. F. Hurst failed to find any cutaneous hyperæsthesia in ten cases of gastric ulcer operated on by Sir Berkeley Moynihan, although the ulcer was present in nine cases out of ten. Leaving out of the question the point as to whether the internal organs are capable of feeling pain, the practical issue for clinicians is the truth or otherwise of Sir James Mackenzie's viscero-sensory and viscero-motor reflexes, and, as you have practically denied the existence of the first, I propose to give some results showing that it exists. The rigid muscle over an inflamed appendix, for instance, is too familiar to require explaining or describing, and I will assume that Dr. Hurst accepts the usual explanation that it is connected in some way or another with the diseased appendix. This is the viscero-motor reflex, and although it is so common it has to be diligently and carefully sought for as one of the indications of disease of an internal organ, and it may even be the only objective sign, which no physician or surgeon would neglect to evalue in making a diagnosis. Now if the truth of the viscero-motor reflex is granted, why should it be doubted for a moment that the tissues immediately above the muscles can be affected in their own proper way and the viscero-sensory reflex excited?

The terms viscero-sensory reflex and viscero-motor reflex are at once a definition and a description, and, like all truths, appeal at once to the mind by their simplicity, and to elicit them no apparatus is required, while the time taken to test them is very short, and if it is the first procedure used in making an examination the time saved is enormous. The importance and significance of the viscero-sensory reflex and the viscero-motor reflex was first impressed upon me by Mackenzie's book, "Symptoms and their Interpretation," but I owe all I know as to the practical application of this knowledge to Mr. D. Ligat, who was induced by Mackenzie to examine all his cases before operation as to the conditions present in the abdominal wall, and then to try to correlate the conditions found at the operation with the symptoms, subjective and objective, that had been noted during the examination. This took place seven years ago, and ever since then I have been looking for this sign, and can say that every abdominal case I have had has been tested for hyperalgesia, and *if there is* one symptom that has been helpful in enabling me to arrive at a diagnosis as to the abdominal organ at fault, it has been this one. That there are tender areas in the abdominal wall in many abdominal diseases is to me, and to many others who practise it daily, a clinical fact there is no disputing.

Before describing the results of my observations it may be well to state my experience with regard to the attitude I have noticed towards this phenomenon amongst my friends. Generally it has been one of indifference, as the procedure has appeared to be much too simple to elicit anything, while others have been interested and *have tried it, but failed* to make anything of it and have given it up. I am convinced now that if a practical demonstration were given on the person of any sceptic and an unsuspected hyperalgesia were found there would never be any doubters as to the reality of this sign. This actually occurred in the person of a relative who had long toyed with the idea until I elicited an area of hyperalgesia over his stomach. Without meaning disrespect to Dr. Hurst, I should say that he failed to find hyperalgesia because he did not know how to apply the test, as I cannot believe that in 10 successive cases of gastric ulcer hyperalgesia was absent. It is quite possible but not probable. In any case its absence in even 10 cases means nothing, as negative results have no significance, while a positive finding is a fact that cannot be disputed. The proper method to be used is the following, the essential feature being that the whole of the tissues down to the deep fascia covering the muscles must be picked up between the finger and thumb and gently but firmly pressed between the opposing digits. The skin and tissues in the flank are first picked up and the amount of pressure estimated that the patient can stand without pain or discomfort. This is used as a standard for comparison with the points at which hyperalgesia may be found. The skin and tissues over these points are then picked up, and if there is hyperalgesia the patient shows it by flinching or moving away, or even by shouting out, so acute may this hyperalgesia be at times.

It may be thought that this sign would only be useful in examining patients of some degree of intelligence, but as a rule the opposite is the case, as, if anything, it is brought out most accurately in children, in whom it is remarkable to see how they never vary in the spots they say are painful, or indicate to be so by flinching, showing conclusively to my mind that the whole abdominal wall is not hyperalgesic, but only specific parts related in some specific way to some specific organ. In children, too, I have watched them come and go during their gastro-intestinal attacks, in which, by the way, the appendix is usually involved as well, and the conclusions I have come to after watching a great number is, that something is left in the appendix after such attacks—the appendix reflex being the last to disappear—and may become a focus from which chronic dyspepsia, so called, results.

The following case will illustrate what I mean:—

A small boy had such a gastro-intestinal attack with involvement of his appendix five years ago and diagnosed as such by the presence of the usual hyperalgesic areas. The attack was all over in two days. I advised an operation but nothing was done. The boy passed out of my care and I did not see him again until last year, when I was asked to examine him as he was suffering from asthma. After examining the chest, without finding anything to account for his asthma, I examined the abdomen and found very definite hyperalgesia over the small gut *area and appendix*, and gave my diagnosis as chronic appendicitis. I was then told that ever since I had seen him five years ago he had had repeated attacks of indigestion, acute and chronic, and that his life had been a misery to him. He was operated on and the diseased appendix removed, since when he has been perfectly well, although hyperalgesia can still be elicited over the small gut area but not over the appendix.

I find in such cases it takes a very long time for the hyperalgesia to disappear from the small gut areas. It indicates the necessity for careful feeding, &c., for some considerable time and gives a warning that the whole trouble is not removed by taking away the appendix. The following case will *help to make clear* the important fact that this sign is not always present even when sought for, and it may help Dr. Hurst to understand that the "necessary stimulus" is not always present even although the lesion is there.

This lady was taken ill with what she called "acute indigestion" while away on a visit. On returning home she consulted her own doctor, who called in an eminent consultant, and her condition was attributed to a floating kidney. The tumour lay under the right rectus, and could be easily palpated. An attempt to replace the tumour in the right loin only resulted in causing great pain and made her medical attendant begin to doubt the diagnosis. He asked for another consultation with his friend, and, as the patient was a friend of mine, she asked me to be present. I saw her and examined her, and found hyperalgesia over the gall-bladder area and some rigidity of the upper right rectus, and came to the conclusion that she had a distended gall-bladder, and gave that as my diagnosis, but it was not accepted, and Mr. Ligat was asked to see her. He knew what I said I had observed, but when he examined her there was no hyperalgesia and no rigidity. Taking all the facts into consideration, however, he advised an operation, and on cutting down a large gall-bladder full of pus and stones was removed.

Now the only reason why I found hyperalgesia and rigidity was because the "necessary stimulus" had been supplied by the manipulation to replace the supposed kidney in the loin, and this had disappeared by the time Mr. Ligat examined her. As Mr. Ligat states in his lecture, the absence of the sign means nothing, but its presence, even if only noted once, is a fact that may count for everything in arriving at a diagnosis, as in this case. Its presence, however, is so constant is certain conditions, that its absence is remarked upon and there is usually some explanation for the fact forthcoming if the case comes to an operation. In "acute abdomens" the necessity to operate is urgent and the absence of an accurate diagnosis is not altogether detrimental to the successful treatment of the case, although if the lesion can be located by the presence of a hyperalgesic area time is often saved which in such cases is of the first importance to the patient.

In this connexion it has been very interesting to read a paper by Mr. Burgess, of Manchester on "Diagnoses of Acute Abdominal Crises,"[1] in which he states that "the presence of these hyperalgesic areas is of very great value in determining the viscus primarily responsible." In chronic cases, however, such as the two mentioned, in children from whom it is difficult or even impossible to get a satisfactory statement of their ailments, or where their aches and pains are; in some cases where there is nothing to guide one as to the nature of the illness or even what organ of the body is involved, an examination of the abdominal wall for the presence of hyperalgesic areas may reveal the nature of the case and suggest the appropriate treatment.

I am, Sir, yours faithfully,
Bexhill-on-Sea, Jan. 25th, 1921. A. MURDOCH.

. Dr. Murdoch leaves one of the chief points at issue out of the question—viz., whether the internal organs are capable of feeling pain. We said nothing about viscero-motor reflexes. Clinicians must decide whether the method of picking up skin and subcutaneous tissues and applying finger-thumb pressure is not open to fallacies on the part both of examiner and examinee. The misreference of pain from viscus to skin was in no way denied as an occasional occurrence.—ED. L.

SEPARATION OF PRESCRIBING AND DISPENSING.

To the Editor of THE LANCET.

SIR,—The Executive of the Association of Certificated Dispensers has had under consideration the discussion recently appearing in THE LANCET appertaining to the separation of prescribing and dispensing. While it agrees with the general principle, it wishes to make it known that there are over 5000 persons holding the Assistant's Certificate of the Society of Apothecaries, London, who are mainly engaged to-day as dispensers to hospitals, institutions, medical practitioners in private practice, &c., and that any attempt on the part of the Pharmaceutical Council or any other body to displace its members to the favour of pharmacists will be strongly opposed. For the information of those of your readers who may not be conversant with the respective functions of the apothecary's assistant and the pharmacist, it is recalled that the pharmacist is primarily licensed to keep open shop for the retailing and dispensing of poisons only, whereas the apothecary's assistant is a qualified dispenser of all substances used in medicine—poisons or otherwise. He was the first and is now the only non-medical person statutorily qualified in professional pharmacy.

I am, Sir, yours faithfully,
H. C. RICHARDS,
Hon. Sec., Association of Certificated Dispensers.
West Croydon, Jan. 28th, 1921.

[1] Brit. Med. Journ., Dec. 11th.

ORAL SEPSIS,

WITH SPECIAL REFERENCE TO ROOT INFECTION.

To the Editor of THE LANCET.

SIR,—Dr. Bertram Watson and Dr. W. H. Willcox have done well to call attention once more in your columns to the importance of chronic infective processes at the apices of the teeth in certain cases of obscure disease. The notion of "pyorrhœa" still holds sway over the minds of most practitioners, and of many dentists also, as being the sole type of dental infection which needs investigation and treatment in relation to general health. Suppurating periodontitis is, of course, of great importance as a cause of divers maladies. But the surface of the gums may be comparatively sound, "pockets" may be conspicuous by their absence, and still there may be deep-seated infection, often non-suppurative, at the apices of dead teeth, whether crowned or not. Such infection is, in my experience, even more important than "pyorrhœa" in connexion with such troubles as arthritis, fibrositis, neuritis, and certain blood infections. I advanced this proposition several years ago, and pointed out the importance of taking cultures from small sacs which form at the roots of dead teeth and from the extreme tips of partially absorbed apices themselves, procedures which not infrequently yield a copious and pure growth of streptococci *even when no suppuration is present.*[1] I brought the subject before the Odontological Section of the Royal Society of Medicine in 1914 in a paper published in the Proceedings of the R.S.M.

As bearing upon Dr. Willcox's letter, I quote the following:—

> "Deep-seated toxic processes are often dependent upon non-suppurating infections when the nidus of the micro-organism is in close contact with the blood stream, as at the roots of the teeth. There may be very little suppuration: quite often there is *no* suppuration at all."

In THE LANCET of 1913 (Vol. I., p. 13) will be found an account of a case of ulcerating endocarditis in which the organism recovered by blood culture was *S. salivarius*. The patient's illness started *after* the removal of a tooth having infection of this kind. This case, and some similar ones that I have published, bear out Dr. Willcox's and Sir William Hale-White's experience, quoted by the former.

Dr. Willcox refers to the importance of X ray examination of suspected teeth. I pointed out in the paper above referred to that a critical examination of the alveolus by the naked eye frequently reveals evidence of root infection which otherwise escapes attention: soft spots in the adjacent gum, patches of congestion and blueness, minute sinuses quite remote from the gum margin, and an unduly broadened or thickened alveolar process as a whole. The presence of stigmata like these gives the practitioner valuable support in the view—which the X ray appearances may confirm—that he is wise in advising the sacrifice of teeth which are mechanically useful. In these days of too reckless extractions on inadequate grounds such confirmation is by no means to be lightly ignored.

I am, Sir, yours faithfully,
Harley-street, W., Jan. 30th, 1921. THOMAS HORDER.

PRESCRIBING AND DISPENSING OF IODINE IN LARGE DOSES.

To the Editor of THE LANCET.

SIR,—The annotation in your issue of Jan. 29th on the administration of large doses of iodine anticipates some notes of mine lately read before the Cambridge Medical Society, but not yet ready for publication; yet further methods practically worked out in its administration may not be amiss at once. The chief one, which, it is only fair to say, I owe to Dr. Mackenzie Wallis at the B.M.A. meeting last June, is to give these large doses in *milk*; the burning of the throat is thus entirely eliminated, the taste is not unlike custard, and it is readily taken. A compound of iodine is certainly formed with the casein, but I have found no difference in the therapeutic effects. When dropped into or mixed with water the iodine is liable to separate out and hang about and burn the throat. Another aid, and one which has the advantage of cheapness in saving spirit, is to order the amount of iodine necessary, exactly the same quantity of iodide of potassium and simple water to make the mixture. In the great majority of patients this small quantity of iodide does not produce iodism; but for those who seem unable to take the smallest quantity of iodide the spirituous form in drops dropped into milk must be ordered. The most susceptible can take it without symptoms of iodism in this form.

---

[1] Clinical Pathology in Practice, 1910.

I am, Sir, yours faithfully,
St. Ives, Huntingdon, Jan. 29th, 1921. W. R. GROVE.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Lieut. L. F. Strugnell to be Surgeon Lieutenant-Commander.

ARMY MEDICAL SERVICE.

Col. L. P. More is placed on half pay.

Col. J. V. Forrest retires on retired pay.

ROYAL ARMY MEDICAL CORPS.

Lieut.-Col. A. E. Master retires on retired pay.

Lieut.-Col. J. D. G. Macpherson is placed on retired pay on account of ill-health contracted on active service.

Major H. T. Wilson relinquishes the acting rank of Lieutenant-Colonel.

Officers relinquishing their commissions:—Temporary Captains retaining the rank of Captain: W. S. T. Neville, A. F. Wyatt, R. Grant, J. Monroe, and L. V. Gatt.

SPECIAL RESERVE OF OFFICERS.

Bt. Lieut.-Col. W. H. G. H. Best is restored to the establishment.

TERRITORIAL FORCE.

Lieut.-Col. P. Paget to be Deputy Assistant Director of Medical Services, 42nd (East Lancs.) Division, with pay and allowances of a Major.

Major C. E. Walker (late R.A.M.C) to be Captain and to relinquish the rank of Major.

Major W. Macdonald resigns his commission and retains the rank of Major.

Capts. C. H. Carlton (late R.A.M.C., Spec. Res.) and D. S. Sutherland (from T.F. Res.) to be Captains.

Capts. T. R. Kenworthy and L. D. Bailey to be Majors.

Capts. W. H. Date and J. Morley resign their commissions and retain the rank of Captain.

Lieut. R. K. Nisbet (late R.A.M.C.) to be Lieutenant.

ROYAL AIR FORCE.

Capt. J. J. O'Mullane is transferred to the unemployed list.

INDIA AND THE INDIAN MEDICAL SERVICE.

Capt. H. H. King has been appointed permanently to the Bacteriological Department. Lieut.-Col. J. H. Hugo has been posted as Residency Surgeon, Kashmir, vice Lieut.-Col. McIver Smith. The following Majors have been promoted Lieutenant-Colonels:—A. G. McKendrick, O. S. J. Moses, F. W. Sumner, H. R. Nutt, W. D. Ritchie, J. Husband, G. C. L. Kerans, H. W. Illius, J. B. Christian, L. P. Brassey, P. L. O'Neill, N. E. H. Scott, J. K. S. Fleming, E. C. Hepper, C. E. Southon, G. Fowler, H. B. Foster, C. B. McConaghy, E. W. Browne, A. Murphy, and C. F. Marr. Lieut. F. W. Matthews, superintendent, Central Prison, Naini, Allahabad, has been appointed to officiate as Civil Surgeon, Rai Barelli. Major J. H. Murray has assumed the duties of Superintendent, Central Jail, Lahore. Capt. C. L. Emmerson, R.A.M.C., has been appointed to officiate as Civil Surgeon, Darjeeling, vice Major A. Denham White, who has proceeded on leave. Major J. D. Sandes, surgeon to the Governor of Bengal, has been granted a year's leave. Major R. Knowles, secretary of the School of Tropical Medicine and Hygiene, Calcutta, has proceeded on eight months' leave. Major R. C. Hallowes has been appointed to the Civil charge of Barrackpore. Major D. P. Watson officiates as Civil Surgeon of Naini Tal during the absence on leave of Lieut.-Col. W. S. Willmore. Major S. C. Chuckerbuty has been posted as Civil Surgeon, Kamrup. Lieut.-Col. M. Corry, civil surgeon, has been appointed Lecturer on Midwifery and Forensic Medicine, and Major R. A. Chambers, principal of the school, Lecturer on Medicine in the Government Medical School at Amritsar. Major R. F. D. Macgregor, medical officer of the Consulate, has been appointed to officiate as His Brittanic Majesty's Consul at Seistan pending the arrival of a successor to Mr. B. J. Gould, who has proceeded on leave. Captain E. S. Goss officiates as an Additional Assistant Director-General, Medical Services, at the Headquarters of the Government of India. Lieut.-Col. H. Ross has been appointed Medical Officer in Charge of the British Mission to Cabul.

ROYAL SOCIETY.—On Thursday, Feb. 10th, the Rev. John Roscoe will read a Résumé of the Results obtained by the Mackie Anthropological Expedition to Uganda.

Obituary.

EDMUND JOHNSON SPITTA, M.R.C.S.,
L.R.C.P. LOND.

ON Jan. 21st the death occurred at Hove—where he had resided since his retirement in 1904—of Dr. Edmund Johnson Spitta, late chairman of the Sussex County Council, and well known as an entomologist and lecturer on natural history. Born in 1853, a son of the late Dr. Robert John Spitta, he was educated at Clapham Grammar School and studied medicine at St. George's, St. Thomas's, and Westminster Hospitals. At St. George's he was a prizeman at the medical school, and acted as senior demonstrator of anatomy. He qualified M.R.C.S. Eng., L.R.C.P. Lond., in 1874, and then for 30 years practised with his father in Clapham.

Spitta was in his earlier years especially interested in photography and astronomy; in 1880 he was made a Fellow of the Royal Astronomical Society, of which he afterwards became vice-president. He was also a prominent member of the Royal Microscopical Society and of the Quekett Microscopical Club, holding the offices of vice-president and president respectively. Notwithstanding the claims of a large general practice Dr. Spitta found, or rather made, time to become not only an expert microscopist but an authority on microphotography. His collaboration with Mr. Charles Slater in the production of an excellent Atlas of Bacteriology, published in 1898, marked the beginning of a long friendship between the joint authors. Dr. Spitta's holidays were organised as photographic expeditions and his family enlisted as assistants. His work on microphotography led to an interest in "process" reproduction, to a very valuable study of microscope objectives, and, after his retirement, to the publication in 1907 of a book on Microscopy, of which a third edition appeared last year. This book treats of the subject from a broad standpoint, teaching by means of admirable diagrams and photographs the principles and laws on which the instrument is constructed, as well as the way to get the utmost possible information from its use. Dr. Spitta also published a book on Photomicrography. He enjoyed making microphotographic films for the kinematograph, and was the first to produce moving pictures of plant and insect life. He devised many ingenious pieces of apparatus, and became very popular as a lecturer on scientific subjects, drawing upon his own large stock of photographs for their illustration. Spitta was especially interested in scientific advances which had a practical and mechanical side. Wireless telegraphy and telephony attracted him so much that he fitted his house with receiving apparatus. His mechanical skill was considerable, and his practical mind went straight for essentials. The subjects which interested him he pursued with immense energy and great thoroughness. No trouble was too great to ensure a good result, and he was a severe critic of his own work. Though this showed the accuracy which we now demand from an expert, in the range and character of his interests he resembled less the modern scientific specialist than the scientific inquirers of an earlier generation, and his versatility was not the least of his striking qualities.

DAVID YELLOWLEES, M.D. EDIN., LL.D. GLASG.

WITH the death of Dr. Yellowlees at Edinburgh on Jan. 19th, in his eighty-fifth year, has passed away a man who combined high professional attainment in mental medicine with a gift for administration. David Yellowlees was born and brought up at Stirling, graduated at Edinburgh in 1857, and after a period of study abroad returned as assistant to Sir William Gairdner at the Edinburgh Royal Infirmary. His first appointment in psychiatry was to assist Dr. Skae at the Edinburgh Royal Asylum, Morningside, and in 1863 he went to direct the Glamorgan County Asylum, where he remained 12 years. In 1874 he followed Dr. Mackintosh as physician superintendent to the Royal Glasgow Asylum, Gartnavel, a post which failing eyesight obliged him to relinquish in 1901. During the greater part of this time he lectured on insanity in the University of Glasgow, which conferred upon him the honorary degree of LL.D. in 1888. He presided over the Psychological Section of the British Medical Association which met at Glasgow in 1885, over the Medico-Psychological Association in 1890, and over the Faculty of Physicians and Surgeons of Glasgow in 1892–94.

Under Yellowlees Gartnavel became a keen centre of psychiatric thought. His physical energy and enthusiasm, combined with a radiant optimism, infected his assistants, as well as in some measure the patients and their friends. His routine was to entrust each of his helpers with the entire responsibility of a part of the asylum, and to hear and discuss their reports at his own house every day at noon. He then visited the wards independently, acting as a kindly and sagacious consultant. Simple and frank himself, he expected, and generally found, the same qualities in others, who grew to rely upon his honest and fearless character.

Dr. Yellowlees took a leading part in the philanthropic work of the city which became his second home. He was for the greater part of his active life on the directing board of the Association for the Relief of Incurables, the Bramhill Home for Incurables, and the Lanfine Home for Consumptives. He helped to found the Glasgow Association for the Care of Defective and Feeble-minded Children, and warmly supported the Glasgow Medical Missionary Society. Work for the protection of women and children always found in him a good friend. All these things were the outcome of deep religious conviction.

After his retirement in 1901 Dr. Yellowlees continued to live in Glasgow until the autumn of 1919, when he returned to Edinburgh to spend the last 18 months of his life. He is survived by his wife, a daughter, and two sons, both of whom are in the medical profession. Dr. David Yellowlees is in practice at Stirling; Dr. Henry Yellowlees is senior assistant physician to the Royal Edinburgh Asylum.

ARTHUR JACKSON, F.R.C.S. ENG.

Mr. Jackson, who died at Shrewsbury on Jan. 9th in his 66th year, had long enjoyed a surgical reputation beyond the county borders. A native of Grays in Essex, he took his medical education at St. Bartholomew's Hospital, London, qualifying in 1878, and becoming F.R.C.S. Eng. in 1882. After filling certain house appointments he went to Shrewsbury to join the late Mr. J. R. Humphreys in partnership, and soon joined him also on the surgical staff of the Salop Infirmary. For nearly thirty years he developed his surgical skill and resource here and at other hospitals and institutions in the neighbourhood, while he was in request as a consultant over a wide area. His death was due to double pneumonia accompanying influenza and following on the news of the sudden death in India of his only son. His widow and a daughter survive him. The memorial service on Jan 12th was attended by a large gathering of medical men.

THE LATE MR. W. L. ROBERTSON.—The death took place at Dundee on Jan. 25th of Mr. W. L. Robertson, who was a well-known surgeon there. Death was the result of septicæmia following a punctured wound on the finger, sustained while performing an operation at the Royal Infirmary on Jan. 17th, but it was not until four days after that Mr. Robertson developed serious symptoms. Mr. Robertson was the eldest son of Mr. J. C. Robertson, C.A., ex-Treasurer of Dundee. After receiving his preliminary education at the High School, he proceeded to St. Andrews University, where he graduated M.A. Subsequently he had a distinguished career in medicine at Edinburgh University, graduating M.B., Ch.B. in 1905, and two years later he obtained the Fellowship of the Royal College of Surgeons of Edinburgh.

Medical News.

UNIVERSITY OF OXFORD.—In a Congregation held on Jan. 20th, the degree of Bachelor of Medicine was conferred on Thomas Sydney Nelson, University College, and Harold George Burford, Christ Church.

The Board of the Faculty of Medicine gives notice that in and after Michaelmas Term, 1921, candidates for the Final B.M. Examination will be required to submit a certificate of attendance at a course of practical instruction in ophthalmology, to include not less than 20 meetings, during a period of three months, at an ophthalmic clinic recognised by the Board.

UNIVERSITY OF LONDON.—*Charing Cross Hospital Medical School.*—A special course of lectures on Fevers. their Clinical and Epidemic Features, Measures of Prevention and Treatment, will be delivered by Dr. William Hunter in the Medical School on Thursdays, at 4.30 P.M., beginning Feb. 10th. The lectures are free to doctors and students of medicine.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—An ordinary Comitia of the College was held on Jan. 27th, Sir Norman Moore, the President, being in the chair. The following were admitted to the Membership of the College: Drs. J. M. H. Campbell, J. H. Dible, M. G. Hannay, B. Hart, F. G. Hobson, Charlotte A. King, D. McAlpine, W. E. Robinson, M. S. Thomson, and W. Wrangham.—Jointly with the Royal College of Surgeons of England diplomas were granted to the successful candidates in public health, tropical medicine and hygiene, psychological medicine, and ophthalmic medicine and surgery.—Dr. A. P. Beddard, Dr. A. J. Hall, Dr. J. W. Russell, and Dr. Gowland Hopkins were elected councillors to take the place of Dr. W. H. Hamer, Dr. A. F. Voelcker, Sir P. Horton-Smith-Hartley, and Dr. F. F. Caiger.—Leave was granted to Dr. A. Gregson Williams to resign his membership and to Mr. H. H. Coates to resign his Licence and Diploma in Public Health.—Dr. W. G. Tyson was nominated delegate to a Congress of the Royal Sanitary Institute to be held at Folkestone from June 20th to 25th.—A memorial received from the Council of the Section of Otology, Royal Society of Medicine, asking the Royal Colleges to grant a Diploma in Otology, was referred to the Committee of Management for report.—The President announced that he had appointed Dr. Herbert Spencer to deliver the Harveian Oration and Dr. Michael Grabham the Bradshaw Lecture in 1921; and the Council had appointed Dr. Major Greenwood to deliver the Milroy Lectures in 1922.—A medal presented to Sir Humphry Rolleston at the centenary of the Académie de Médecine, was given by him to the College.—Representatives of the College were appointed on the following bodies: Central Midwives Board, Sir Francis Champneys; Court of Governors of Liverpool University, Sir Dyce Duckworth reappointed; Court of Governors of Birmingham University, Dr. Voelcker; Committee of Management of the Chelsea Physic Garden, Sir George Savage reappointed; Conjoint Board of Scientific Societies, the President and Dr. H. Head reappointed; Central Council for District Nursing in London, Sir William Hale-White reappointed.—Acting on a report from the Committee of Management the Technical College, Bradford, was recognised for the course of laboratory instruction for the Diploma in Public Health, and the William Ellis Endowed School, Gospel Oak, N.W., Ipswich School, and the Municipal College, Burnley, were added to the list of institutions recognised for instruction in chemistry, physics, the last-named also in biology; the Infectious Diseases Hospital, Cambridge, was added to the list of fever hospitals recognised by the Conjoint Board; and the special course of three months' study of advanced public health at Haslar was recognised as sufficient to reduce to three months the instruction under a medical officer of health required for the Diploma in Public Health.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—Diplomas have been conferred upon the following candidates who have passed examinations in the undermentioned subjects:—

DIPLOMA IN PSYCHOLOGICAL MEDICINE.

Mostafa Dia, Cairo and St. Mary's; Edmund Duncan Tranchell Hayes, Trin. Coll., Dublin; Owen Sidney Martin, Univ. Coll.; and Henry William Parnis, Malta.

DIPLOMA IN OPHTHALMIC MEDICINE AND SURGERY.

Joseph Ringland Anderson, Melbourne Univ. and Royal London Ophth. Hosp.; Robert Smith Candlish, Sydney and Western Ophth. Hosp.; Kamil Maximus Labiebe, Manchester and Royal London Ophth. Hosp.; William Oliver Lodge, Leeds; Behram Hormusji Pesikaka, Royal London Ophth. Hosp.; Syed Abdur Rahim, Bombay and Royal London Ophth. Hosp. and George Zachariah, Royal Eye Hosp., Southwark.

Royal College of Surgeons of England.—The following lectures are to be delivered in the theatre of the College, Lincoln's Inn-fields:—Two Hunterian lectures on the Surgery of the Peripheral Nerve Injuries of Warfare, by Professor Harry Platt, on Feb. 7th and 9th; one Hunterian lecture on a Research into the Pathology and Ætiology of Loose Bodies Composed of Cartilage or of Cartilage and Bone occurring in Joints, by Professor A. G. Timbrell Fisher, on Feb. 11th; one Arris and Gale lecture on the Cause and Prevention of Myopia, by Dr. F. W. Edridge-Green, on Feb. 16th. These lectures will be given at 5 P.M. On Monday, Feb. 14th, at 4 P.M., the Hunterian oration will be delivered by Sir Charters J. Symonds. Fellows and Members of the College are invited to attend.

Post-Graduate Lectures for London Panel Practitioners.—Further courses in clinical pathology and venereal diseases are being arranged during the spring, and practitioners wishing to attend them are desired to send in their names to the secretary of the Panel Committee. The fee for each course is £3 3*s.*

London Hospital Medical College.—Dr. Percy Kidd, consulting physician to the London Hospital, has been elected Schorstein Memorial Lecturer for 1922. The lecture for 1921 will be delivered on June 3rd by Dr. A. G. Gibson, who has chosen as his subject Chronic Inflammatory Diseases of the Spleen.

Hunterian Society.—The annual oration will be delivered by Dr. Henry Howarth Bashford on "The Ideal Element in Medicine" on Wednesday, Feb. 16th, at 9 P.M., at the Sion College, Embankment, London, E.C. All members of the medical profession are invited to attend.

Medical Coroner.—Dr. William Bentley Purchase has been appointed deputy coroner for the Eastern District of London.

No. 19 C.C.S.: Annual Dinner.—The second annual dinner will take place on Feb. 19th, at the Refectory Restaurant, Golders Green, London. Those wishing to be present are asked to apply for tickets (15*s.*) to the Rev. E. C. Doddrell, 6, Alexandra House, Regent's Park-road, Finchley, N. 3.

National Dental Hospital: Annual Dinner.—The annual dinner of the Students' Society was held at the Hotel Cecil, London, on Jan. 27th. The chairman was Mr. A. B. G. Underwood, sub-dean of the school, who was supported by Sir Kenneth Goadby, Mr. Peter Sidney Spokes, Dr. George Blacker, Mr. Relph, Dr. Dudley Buxton, Dr. J. Strickland Goodall, Mr. J. L. Dudley Buxton, Dr. C. J. Ogle, Dr. J. Maughan, and Dr. H. Pinto-Leite. After the usual toasts had been honoured, a presentation was made to Mr. Spokes by the chairman on behalf of the staff of the National Dental Hospital and other subscribers. Mr. Underwood referred to the great services to the hospital of Mr. Spokes. These extended over a period of 33 years. He had held the office of dean of the school since 1891, and it was mainly through his efforts that the present amalgamation with University College had been carried out, the National Dental Hospital now being the dental school of University College. Mr. Spokes suitably replied. Mr. R. Lindsay gave the toast of "The Students' Society," and Dr. Pinto-Leite proposed "The Visitors" and Mr. E. H. Lawrence "The Chairman." Dr. Blacker and Mr. Underwood responded.

Medical Officers of Schools Association.—A general meeting of this association will be held at 11, Chandos-street, Cavendish-square, London, W., on Feb. 15th, at 4.45 P.M., when a paper will be read by Dr. E. H. T. Nash on "School Punishments." Preparatory to this meeting a questionnaire has been circulated amongst the members of the association. The questions are:—

1. What form or forms of corporal punishment are in use at your school? 2. By whom are they administered? 3. With what are they administered? 4. Is corporal punishment reserved for any special offences? 5. Are any regulations laid down by the authorities, or is each master free to use his own discretion? 6. Do you approve of caning on the hand? Please give reasons for or against. 7. *Have you seen any ill*-results from caning on the hand? If so, what? 8. Have you seen any ill-results from caning on the buttocks, or from any other form of corporal punishment in use at your school? 9. Please state what form of corporal punishment you, as an S.M.O., believe to be the most effective and least liable to produce harmful results. 10. Please state what forms of punishment are in use at your school other than corporal punishment, and what your personal opinions are as to the effect on the pupil. 11. Have any cases come to your notice where corporal punishment has had an unsatisfactory result on the pupil apart from the physical effect? 12. Any *personal opinions* on the matter apart from the foregoing questions will be welcomed.

A general conference of school medical officers, educationists, and others will be convened at a later date to discuss such conclusions as may be reached on Feb. 15th.

Donations and Bequests.—A donation of £12,000 has been received by the Manchester Royal Infirmary from the National Relief Fund, £158 in legacies, and £145 in other donations.—The St. Mary's Hospitals, Manchester, have received £1750 from the Women's Guild of Service, and other donations to the amount of £433.

University of Aberdeen.—A special graduation ceremony took place in Marischal College, Aberdeen, on Jan. 25th, when the graduates in the special final medical examination held last term had their degrees conferred upon them. The capping ceremony was performed by Principal Sir George Adam Smith, Vice-Chancellor, and the graduands were presented by Professor C. R. Marshall, Dean of the Faculty of Medicine.

Scottish Midwives Board.—The Central Midwives Board for Scotland as constituted under the Act of 1915 will consist from Feb. 1st of the following members, the appointing body being given before the name or names:—

Scottish Board of Health, three members, two of whom shall be midwives practising in Scotland: Miss Alice Helen Turnbull, superintendent health visitor, Maternity and Child Welfare Department, Edinburgh. *Practising:* Miss Isabella Lewis Scrimgeour, superintendent, Cottage Nurses' Training Home, Govan; Miss Kate Leslie Scott, chairman of Council of Scottish Midwives' Association, Aberdeen.

Association of County Councils for Scotland: Sir Archibald Buchan-Hepburn, *convener of Haddington County Council.*

Convention of Royal Burghs of Scotland: Sir Robert Cranston, Edinburgh.

Queen Victoria Jubilee Institute for Nurses, Scottish Branch: Dr. James Haig Ferguson, Edinburgh.

Society of Medical Officers of Health of Scotland: Dr. A. Campbell Munro.

University Courts of Edinburgh and St. Andrews, one member, conjointly, Dr. J. A. C. Kynoch, Professor of Midwifery, St. Andrews.

University Courts of Glasgow and Aberdeen, one member, conjointly: *Dr. Robert Gordon McKerron, Professor of Midwifery*, Aberdeen.

The Royal Colleges, one member, conjointly: Dr. Robert Jardine, Glasgow.

Scottish Committee of British Medical Association; Dr. Michael Dewar, Edinburgh; Dr. E. H. L. Oliphant, Glasgow.

Society for the Prevention of Hydrophobia.—A meeting of the committee of this society was held at the Farmers' Club, Whitehall Court, London, on Feb. 1st. Mr. F. W. Fletcher, acting honorary secretary, reported the deaths of Dr. Sidney Turner, the late chairman of the committee, and of Mr. Frank Karslake, the late honorary secretary. The committee then appointed Major J. Penberthy chairman and Mr. Fletcher honorary secretary. Major Penberthy, from the chair, drew attention to the great services rendered to the society by the late Dr. Turner and the late Mr. Karslake, and said that this was also the first opportunity the committee had had of referring to the services of the late Sir Victor Horsley, who had preceded Dr. Turner as chairman and had taken such an active part in the work of the society. A motion was placed on record expressing the committee's sense of the great losses the society had sustained. The minutes of the last meeting of the committee, held in July, 1919, were then read and a financial statement was received from Mr. F. B. Debenham, honorary treasurer, from which it appeared that the society's expenditure from May, 1919, when activities were recommenced, to the end of December, 1920, had been £60 5*s.* 1*d.*, leaving a debit balance of £8 17*s.* 6*d.* The principal item of expense had been the printing of 1000 copies of the booklet on Rabies and Hydrophobia, of which a number were still available at 1*s.* each. The committee then considered what steps should be taken with regard to the renewed outbreaks of rabies which during the past two years have occurred in various parts of the country. It was pointed out that these have probably originated from the smuggling of dogs into the country from the continent, the Air Service affording ample opportunity for this deplorable practice. Fines had no deterrent effect, and it was the intention of the committee to urge the Government to make such smuggling a penal offence. The futility of recent endeavours to stamp out rabies by muzzling dogs in limited areas had again been demonstrated, and until the policy advocated by the society of universal muzzling of dogs for a definite period was adopted, the disease would never be eradicated. Propaganda was indispensable for the enlistment of public support, and a certain amount of expenditure was therefore necessary. The society had no paid officials, the whole of the work entailed being honorary; it was, however, important that the existing deficit be cleared off and that the treasurer should have funds in hand to meet future expenses; it was therefore decided to issue a report setting forth the financial position to members of the society. After a short discussion with reference to the formation of a council and the possibility of strengthening the executive committee, the meeting closed.

Payment for Medical Services at a Voluntary Hospital.—The Great Northern Central Hospital has now graded its accommodation into three sections. In the general wards (140 beds) necessitous cases are admitted free, but patients who can *afford to do so give* 1*s*. to 20*s*., according to circumstances. Patients in the contributory wards (62 beds) pay £1 1*s*. to £4 4*s*., according to their means, as assessed by the committee. The treatment of patients in the *general and contributory* wards is undertaken gratuitously by the honorary medical staff. The recently inaugurated private wards (18 beds) are intended for patients whose means do not allow of the payment of the usual *medical and surgical fees*, but who are willing to contribute towards the cost of medical services and of maintenance while in the hospital. The payments range from 4½ to 6 guineas per week, with a fee for medical service of £1 1*s*. per visit—maximum fee for medical service £3 3*s*. per week. For an operation £5 5*s*. will be payable to cover the reduced fees of the surgeon and the anæsthetist and the charge for the use of the theatre. By arrangement with a member of the honorary medical staff and the patient concerned private practitioners may attend the hospital to share in the treatment. The patient in this case pays the local medical practitioner's fee. In assessing the amount payable by patients the committee will arrange for a rebate of 50 per cent. off the medical fees where the income is the minimum for the private wards or exceeds the minimum by not more than £100.

Admission of Paying Patients to Liverpool Poor-law Hospital.—The guardians of the West Derby Union in the city of Liverpool, with a view to relieve the pressure on accommodation of the voluntary hospitals, have decided to set apart a certain portion of the buildings of their hospital in Mill-road *for the treatment of paying* patients, male or female adults, who reside within the West Derby area and who are suffering from acute disease of a non-infectious or non-contagious character. It is intended to make an inclusive charge of 3 guineas per week for the maintenance and treatment of each patient. This will benefit many who, while unable to receive prompt admission *into one of the* voluntary hospitals, cannot afford to pay the usual fees of the nursing homes. It is anticipated that the sum of 3 guineas will be sufficient to cover the maintenance and treatment of these patients, who will be dealt with on the lines of private patients. *For their treatment* the operating theatre of the hospital will be available, and X ray, electro-therapeutic, and massage departments. The hospital is under the administration of a medical superintendent, who is assisted by three resident medical officers and a visiting staff of specialists. The guardians state that this scheme will not lessen except in a minor degree the accommodation available for the destitute sick. By arrangement with the medical superintendent it will be possible for the patient's own doctor or for any specialist he may desire to consult with the ordinary medical staff of the hospital.

Royal Southern Hospital, Liverpool: Dinner to Sir Robert Jones.—Under the chairmanship of Lord Derby, over 200 friends and colleagues of Major-General Sir Robert Jones assembled in the Adelphi Hotel, Liverpool, on Jan. 31st to entertain him to dinner and present him with his portrait in oils, subscribed *for by the* committee and staff of the Royal Southern Hospital. The gathering was a tribute to the popularity of the guest of the evening; former residents of his had come from all parts of the country to be present; not only were Liverpool surgeons present, but Sir Berkeley Moynihan came from Leeds, and a letter of apology from Sir Anthony Bowlby regretted his unavoidable absence. After the loyal toasts the chairman proposed the toast of "The Guest"; he spoke in terms of the highest appreciation of Sir Robert Jones's work among crippled children, and then passed on to show how the coping-stone had been added to his life's work by the help he had rendered to the crippled and disabled soldiers during and since the war. Under his magnetic spell, and in consequence of his genius for organisation, orthopædic hospitals had been opened in all the great centres in the country, and new hope had been brought into the lives of many a disabled man. Mr. G. P. Newbolt, senior surgeon to the Royal Southern Hospital, in supporting the toast, recalled many interesting incidents in the life of Sir Robert Jones and himself when they had worked together first at the Stanley Hospital and afterwards as surgeons to the men engaged in constructing the Manchester Ship Canal, and he bore high testimony to the lovable qualities of the guest as a colleague and a friend. The toast was pledged with enthusiasm, after which the chairman unveiled and presented the portrait. Sir Robert Jones, who received a great ovation, paid a tribute to the late and great Hugh Owen Thomas, that pioneer in orthopædic surgery whose splint had been the means of reducing the mortality of fracture of the thigh in the war from 80 20 per cent., and he bore witness to the help and encouragement he had received from the chairman as Minister for War in his work of organising the orthopædic centres throughout the country. The following toasts were then honoured: "The Royal Southern Hospital," proposed by Dr. J. Gemmell, President of the Liverpool Medical Institution, and responded to by Mr. Thomas Woodsend, President of the Hospital Committee; "The Guests," proposed by Dr. C. J. Macalister and responded to by Vice-Chancellor J. G. Adami and Sir Berkeley Moynihan; and "The Chairman," proposed by Mr. T. R. W. Armour; to whose work as organising secretary the success of the banquet was largely due.

Lord Mayor of Bristol's Hospital Sunday Fund.—In an appeal for the collection undertaken on Jan. 30th on behalf of this fund, it is stated that in the four chief voluntary hospitals of the city—the General Hospital, the Royal Infirmary, the Children's Hospital, and the Eye Hospital—103,065 patients were treated last year at a cost of £90,792, being nearly £57,501 more than the income. Last year's collection reached a record total of over £6000.

East Grinstead Dispensary.—At the sixty-second annual meeting of this dispensary it was stated that from 1912 onwards the income had only once met the expenditure, and then only with a balance of £1. To meet these yearly deficits the reserve fund had been drawn upon. Three possible courses of action—to continue as at present until the reserve be exhausted, to appeal for funds, or to close down—were considered by the subscribers, and by a unanimous vote it was decided to approach the local Cottage Hospital with a view to amalgamation, and to carry on meanwhile.

R.A.M.C. (T.) Concert at Birmingham.—The annual supper and smoking concert of the Royal Army Medical Corps, Territorial Units of Birmingham, was held at the *White Horse Hotel, Birmingham, on Jan.* 28th, Lieutenant-Colonel C. H. Howkins, R.A.M.C., presiding. The chairman pointed out the great strides that had been made in recruiting for the units since the New Year and the *indication* there was that these units would shortly be at full peace strength. About 100 members were present and an excellent programme of music was provided.

Manchester Royal Eye Hospital.—This hospital is feeling severely the greatly increased cost of upkeep. In spite of an unexpected gift of £5000 from the National Relief Fund, *the year finished with an adverse balance* of £3715, and this takes no account of the sale of certain securities. The St. John-street out-patient department is closed. Its sale will realise a useful sum, but the amount obtained is required for *a* new out-patient department *on* a site already secured opposite the hospital.

Sir George Makins at Belfast.—On Jan. 27th Sir George Makins gave an address to the Ulster Medical Society on "Injuries to the Heart," the President, Dr. Thomas Houston, being in the chair. The address dealt with the experience *garnered in the late war, and* was one of exceptional interest and importance. A vote of thanks to the lecturer was passed by Professor T. Sinclair and seconded by Dr. J. Walton Browne. On Jan. 28th Sir George Makins addressed a meeting of the Belfast Medical Students' Association on "Our Profession," the President of the association, Professor W. St. C. Symmers, being in the chair. There was a crowded attendance of students of both sexes, and the distinguished visitor had an enthusiastic reception. The speaker dealt first with some of the phases of medical education, and pointed out some of the advantages of the old apprenticeship system. He emphasised the importance of practical experience with disease at the earliest stage in the student's career, and expressed his *preference for the older* system under which the student was introduced to hospital work while still engaged in the study of the preliminary subjects. He thought that danger lurked in the multiplication of specialised methods of examination, and pointed out that a fallacy might exist even in a Wassermann reaction. The laboratory worker was no more exempt from error than was the clinician. The large *majority of medical students* became general practitioners, and would often practise in places where they could not command the services of the pathologist or the radiologist. There was the more reason to cultivate the older methods of observation and diagnosis, which were always available. He thought that in many respects the career of the general practitioner was a more desirable one than that *of the* specialist. *The general* practitioner in many cases knew his patients from the cradle and was their trusted friend and adviser, while the relations of the specialist to his patients were slight and casual. In contrasting the surgeon and the physician he thought that while in these days the surgeon had the advantage financially, the physician was in most cases the more learned man.

COMMITTEE ON VOLUNTARY HOSPITALS.—A meeting of Lord Cave's Committee on Voluntary Hospitals was held on Feb. 2nd at the Ministry of Health, when evidence was given in the morning by Sir Cooper Perry and Mr. Maynard on behalf of the King Edward VII. Hospital Fund, and in the afternoon by Mr. Verity, chairman of Charing Cross Hospital. Evidence is to be taken from Mr. Vernor Miles on behalf of the small general hospitals in the London area.

CHILD-STUDY SOCIETY.—A lecture on Vocational Tests will be given by Mr. C. H. Miles, D.Sc., at 90, Buckingham Palace-road, London, S.W., on Thursday, Feb. 10th, at 6 P.M.

MEDICO-LEGAL SOCIETY.—A meeting of this society will be held at 11, Chandos-street, London, W., on Tuesday, Feb. 15th, at 8.30 P.M., when a paper will be read by Dr. Halliday Sutherland on Medical Evidence in the Staunton Murder Trial.

No. 14 GENERAL HOSPITAL: REUNION DINNER.—A reunion dinner of the staff (medical officers, sisters, and V.A.D.'s) of No. 14 General Hospital (Wimereux) will be held at the Ladies' V.A.D. Club, 28, Cavendish-square, London, W., at 7.30 P.M., on Wednesday, March 16th, Sir John Goodwin presiding. Application for tickets, price 15s, inclusive, should be made to Miss Sloggett, 6, Bickenhall Mansions, London, W. 1.

ENCEPHALITIS LETHARGICA.—The Registrar-General's latest return shows that 21 cases of encephalitis lethargica were notified in London during the week ending Jan. 22nd. Of these 5 occurred in Stepney and 2 each in Fulham, Lambeth, and Southwark. Sixteen cases have been reported in Manchester during the last month. A fatal case of a man, aged 24, occurred at Mossley, after being asleep for 11 days. Another fatal case occurred in the Union Infirmary, Oldham, at the end of the week, the victim being a young woman, who had been asleep for 10 days before her death.

Appointments.

HENRY, LYDIA M., M.D. Shef., has been appointed Assistant Medical Officer for Blackburn.

MORLEY, J., Ch.M. Vict. Manch., F.R.C.S. Eng., Honorary Assistant Surgeon, Manchester Royal Infirmary, Manchester.

WHITEFORD, C. HAMILTON, M.R.C.S., L.R.C.P. Lond., Consulting Surgeon to the Great Western Railway, Plymouth Centre.

WYNNE, F. E., M.B., B.Ch. Dubl., D.P.H., Medical Officer of Health for Sheffield.

West London Hospital: STEWART, T. G., M.D. Edin., Physician; PINCHIN, A. J. S., M.D. Lond., Assistant Physician; PATERSON, H., Medical Registrar; DAVIES, T. B., M.D. Lond., Obstetric Registrar.

Vacancies.

For further information refer to the advertisement columns.

Aberdeen Dispensary and Vaccine Institution.—Hon. M.O.

All Saints' Hospital for Genito-Urinary Diseases, 19/57, Vauxhall Bridge-road, S.W.—Res. H.S. £200.

Belgrave Hospital for Children, Clapham-road, S.W.—Asst. P. 50 gs.

Birmingham, Dudley-road Hospital.—Res. Asst. M.O. £413.

Bootle Borough Hospital.—Sen. and Jun. H.S.'s. £200 and £150.

Brighouse Borough.—M.O.H. and Sch. M.O. £650.

Burnley County Borough.—Female Asst. M.O.H. £500.

Cardiff, King Edward VII. Hospital.—Hon. Asst. Ophth. S.

Croydon County Borough.—Res. Med. Supt., Sanatorium, North Cheam. £500.

Dreadnought Hospital, Greenwich.—H.P. and H.S. £150.

East Ham Education Committee.—Sch. Dentist. £450.

Eccles and Patricroft Hospital.—Res. H.S. £200.

Exeter, Royal Devon and Exeter Hospital.—P. and S.

Federated Malay States Colonial Service.—Pathologist to the Medical Research Institute. £1050.

Glasgow Education Authority.—Dentist. £400.

Glasgow, Woodilee Mental Hospital, Lenzie, near Glasgow.—Asst. M.O. £350.

Great Yarmouth Hospital.—H.S. £250.

Greenwich and Deptford Practitioners L.C.C. School Clinic Committee, 82, Park-row, Greenwich, S.E.—Refract., P., Aural S., and Anæsth. £80.

Hastings Education Committee.—Asst. Sch. M.O. £500.

Holborn Metropolitan Borough.—M.O.H. £1000.

Hull Royal Infirmary.—Asst. H.S. £150.

Italian Hospital, Queen-square, W.C.—Officer-in-Charge of X Ray Department.

Kent, Borough of Bromley.—M.O.H. £750.

Kent Education Committee.—Female Sch. Med. Inspec. £500.

King's College Hospital, Denmark Hill, S.E.—Jun. Anæsth.

Kingswood, Bristol, Cossham Memorial Hospital.—Visiting S.

Leeds General Infirmary.—M.O. £100.

Leicester Royal Infirmary.—H.S. £200.

London Hospital.—Demonstratorship in Minor Surgery. £200.

London (Royal Free Hospital) School of Medicine for Women and Royal Free Hospital.—First and Second Assts. in Gynæc. and Obst. Unit. £700 and £500.

Loughborough and District General Hospital and Dispensary.—Res. H.S. £200.

Macclesfield, Cheshire County Asylum, Parkside.—Asst. M.O. £350.

Maidstone, Kent County Mental Hospital.—Asst. M.O. £350.

Manchester, Children's Hospital, Pendlebury, near Manchester.—Asst. S. £50.

Manchester Royal Infirmary.—H.S. to Special Departments. £50. Also Jun. Anæsth. £100.

Miller General Hospital for South-East London, Greenwich-road, S.E.—Hon. Asst. P.

National Hospital for the Paralysed and Epileptic, Queen-square, Bloomsbury, W.C.—Res. M.O. £200.

Netherne Mental Hospital, Coulsdon, Surrey.—Asst. M.O. £400.

Newark Hospital and Dispensary.—Res. H.S. £200.

Newcastle-upon-Tyne, Royal Victoria Infirmary.—Res. Anæsth. £120.

Newport, Mon., Royal Gwent Hospital.—H.S. £200.

Northumberland County Asylum, Morpeth.—Asst. M.O. £400.

Oldham Royal Infirmary.—Third H.S. £200.

Peterborough General Infirmary.—H.S. £150.

Plymouth, South Devon and East Cornwall Hospital.—H.P. £175. Also Asst. S.

Plymouth Workhouse and Infirmary.—Res. Asst. M.O. £300.

Portsmouth Royal Hospital.—H.S. £150.

Queen Charlotte's Lying-in Hospital, Marylebone-road, N.W.—Obst. S.

Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Res. M.O. £200. H.S. £100.

Queen Mary's Hospital for the East End, Stratford, E.—Hon. Ophth. S.

Royal London Ophthalmic Hospital, City-road, E.C.—Pathologist and Curator. £200. Also Sen. H.S. £150.

Royal Waterloo Hospital for Children and Women, S.E.—Cas. O. £150.

Saffron Hill Maternity Centre.—Hon. P.

St. Bartholomew's Hospital.—P.

St. Bartholomew's Hospital Medical School.—Chair of Anatomy. £900.

St. Mary's Hospital, Paddington, W.—Electro-therapeutic O.

St. Peter's Hospital, Henrietta-street, Covent Garden, W.C.—Hon. M.O.

Sheffield Royal Infirmary.—Asst. Cas. O. £150

Singapore, Straits Settlements.—Asst. Principal of Medical School. $600 per month.

Stannington (Northumberland) Children's Sanatorium.—Female Res. M.O. £250.

Sunderland Royal Infirmary.—Two Jun. H.S.'s. £200.

University of London.—External Examiners.

West Bromwich and District Hospital.—Res. Asst. H.S. £200.

York Dispensary.—Res. M.O. £250.

THE Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at Portree, Horbury, and Penmaenmawr.

Births, Marriages, and Deaths.

BIRTHS.

DREW.—On Jan. 30th, at a nursing home, Chester, the wife of Major C. M. Drew. D.S.O., R.A.M.C., of a son.

MANDEL.—On Jan. 26th, at Harley-street, W., the wife of Dr. Leopold Mandel, M.D., M.R.C.P., of a daughter.

MATTHEWS.—On Jan. 27th, at Onslow-square, the wife of Dr. Guy Matthews, of a son.

RICE-OXLEY.—On Jan. 31st, at Victoria-road, Kensington, W., the wife of Douglas Rice-Oxley, M.C., M.B., B.S., of a son.

MARRIAGES.

HINCKS—MCGILLYCUDDY.—On Jan. 25th, at New Malden, Surrey, A. Cecil Hincks, M.C., M.B., Ch.B., to Ethel Florence, widow of Major R. H. McGillycuddy, M.C., R.A.M.C.

DEATHS.

DAYUS.—On Jan. 26th, at Cumberland Lodge, Romford Road, Forest Gate, after a short illness, Frederick Herbert Dayus, M.R.C.S. Eng., L.R.C.P. Lond., aged 52.

HASSALL.—On Jan. 31st, at The Dingle, Manor-road, Worthing, John Hassall, M.D., M.R.C.S., F.R.M.S., *aged 65 years.*

WRIGHT.—On Jan. 29th, at Mountsorrel, Romford, Alfred Wright, M.R.C.S., L.S.A., J.P., aged 81.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

BOOKS, ETC., RECEIVED.

SOCIETIES.

ROYAL SOCIETY, Burlington House, London, W.

Thursday, Feb. 10th.—Paper:—The Rev. J. Roscoe: A Résumé of the Results obtained by the Mackie Anthropological Expedition to Uganda.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, Feb. 8th.

SECTION OF PSYCHIATRY: at 8.30 P.M.

Paper:

Dr W. A. Potts: Mental Tests.

Wednesday, Feb. 9th.

SECTION OF SURGERY: SUBSECTION OF PROCTOLOGY: at 5.30 P.M.

Case:

Sir Charles Gordon Watson: Fistulæ treated by Excision and Primary Suture.

Papers:

Mr. W. B. Gabriel: The Results of an Experimental and Histological Investigation into 75 Cases of Rectal Fistulæ. (Showing Sections and Cases of Proved Tuberculous Fistulæ.)

Mr. H. Graeme Anderson: Method of Abdomino-perineal Excision of the Rectum in Three Stages.

Thursday, Feb. 10th.

SECTION OF NEUROLOGY.

Clinical Meeting at 8 P.M., at the National Hospital for Paralysis and Epilepsy, Queen-square, W.C. 1.

Those Members who wish to show cases should communicate with the Hon. Secretary, Dr. P. W. Saunders, at the Hospital.

Friday, Feb. 11th.

CLINICAL SECTION
SECTION OF MEDICINE } Joint Meeting: at 5 P.M.
SECTION OF SURGERY

Discussion:

On "The Medical and Surgical Treatment of Graves' Disease" (to be opened by Dr. Hector Mackenzie and Mr. James Berry).

Other Speakers:—Prof. George R. Murray, Sir William Hale-White, Mr. T. P. Dunhill, Mr. Donald Armour, Dr. J. M. H. Campbell, Dr. Florence Stoney, Dr. Hernaman-Johnson, and Mr. W. H. C. Romanis.

The Hon. Secretaries will be glad to learn of other Members who wish to contribute to the discussion.

SECTION OF OPHTHALMOLOGY: at 8.30 P.M. (Cases at 8 P.M.)

Papers:

Mr. B. T. Lang: Scotometry.

Dr. T. Harrison Butler: Late Infections after Sclerectomy.

Mr. M. L. Hepburn: Some Notes on Trephining.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

Monday, Feb. 7th.—9 P.M., Lettsomian Lecture (I.):—Mr. G. E. Gask: Surgery of the Lung and Pleura.

BIRMINGHAM MEDICAL PSYCHOLOGICAL SOCIETY.

Wednesday, Feb. 9th.—4.15 P.M., Paper:—Dr. D. Gillespie: The Symptoms of an Epileptiform Attack.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.

Monday, Feb. 7th, and Wednesday.—5 P.M., Hunterian Lectures:—Prof. H. Platt: The Surgery of the Peripheral Nerve Injuries of Warfare.

Friday.—5 P.M., Hunterian Lecture:—Prof. A. G. T. Fisher: A Research into the Pathology and Ætiology of Loose Bodies composed of Cartilage or of Cartilage and Bone occurring in Joints.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

Monday, Feb. 7th.—2 P.M., Mr. B. Harman: Eye Department. Dr. S. Pinchin: Medical Out-patients. Dr. Morton: X Ray Department. 5 P.M., Lecture:—Dr. A. Saunders: The Digestive Disturbances of Old Age.

Tuesday.—10 A.M., Mr. Steadman: Dental Department. Dr. McDougal: Electrical Department. 2 P.M., Mr. Banks Davis: Diseases of the Throat, Nose, and Ear. 5 P.M., Lecture:—Mr. Baldwin: Appendicitis.

Wednesday.—10 A.M., Mr. MacDonald: Genito-Urinary Department. 2 P.M., Mr. Addison: Operations. Dr. Burnford: Demonstration of Cases (Medical Wards). 5 P.M., Lecture:—Mr. D. Armour: Physical Signs and Diagnosis of Abdominal Tumours.

Thursday.—10.30 A.M., Dr. Simson: Gynæcological Demonstration. 2 P.M., Mr. MacDonald: Surgical Out-patients. Mr. B. Harman: Eye Department. 5 P.M., Special Lecture:—Dr. C. Porter: Epidemic Diarrhœa (open to all medical practitioners).

Friday.—2 P.M., Mr. T. Gray: Surgical Out-patients. Dr. Pernet: Skin Department. 2.30 P.M., Mr. Addison: Visit to Surgical Wards. 5 P.M., Lecture:—Mr. Baldwin: Appendicitis.

Saturday.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 12 noon, Mr. Sinclair: Surgical Diseases of the Abdomen. 2 P.M., Dr. Owen. Medical Out-patients.

Daily:—10 A.M. Ward Visits. 2 P.M., In-patient, Out-patient Clinics and Operations.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Monday, Feb. 7th.—10 A.M., Mr. W. E. Tanner: Surgical Out-patients. 2 P.M., Dr. A. J. Whiting: Medical Wards. 2.30 P.M., Mr. E. Gillespie: Surgical Operations. Mr. J. B. Banister: Gynæcological Out-patients. Dr. J. B. Alexander: Medical Out-patients. 4.30 P.M., Clinical Demonstration:—Mr. J. B. Banister: Heart Disease in Pregnancy. 6 P.M., Dr. F. L. Provis and Mr. T. H. C. Benians: Venereal Department.

Tuesday.—9.45 A.M., Lieut.-Col. R. H. Elliot and Mr. N. Fleming: Eye Operations. 2.30 P.M., Mr. H. W. Carson: Surgical Operations. Mr. C. H. Hayton: Diseases of the Throat, Nose, and Ear. Dr. Metcalfe: X Ray Department. 3 P.M., Clinical Demonstration:—Dr. J. Metcalfe: Treatment of Surface Disease by Electrolysis. 5.30 P.M., Dr. C. E. Sundell: Children In-patients.

Wednesday.—2 P.M., Mr. C. H. Hayton: Throat Operations. 2.30 P.M., Dr. W. J. Oliver: Skin Department. Dr. J. B. Alexander: Medical Out-patients. 4.30 P.M., Clinical Demonstration:—Mr. N. Fleming: Cases of Eye Disease. 5 P.M., Dr. Provis and Mr. Benians: Venereal Department.

Thursday.—2.30 P.M., Mr. N. Fleming: Eye Out-patients. Dr. A. J. Whiting: Medical Out-patients. Mr. H. W. Carson: Surgical Out-patients. Mr. J. B. Banister: Gynæcological Operations. Dr. J. Metcalfe: X Ray Department. 3 P.M., Clinical Demonstration:—Dr. C. F. Hadfield: Anæsthetic Demonstration.

Friday.—2 P.M., Mr. Howell Evans: Surgical Operations. 2.30 P.M., Dr. C. E. Sundell: Children Out-patients. Mr. E. Gillespie: Surgical Out-patients. 3 P.M., Clinical Demonstration:—Mr. T. H. C. Benians: Diagnostic Methods of Clinical Pathology. 5 P.M., Dr. Provis and Mr. Benians: Venereal Department.

Saturday.—3 P.M., Mr. H. W. Carson: Surgical In-patients.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, W.C. 1.

MEDICAL SCHOOL.

Monday, Feb. 7th.—2 P.M., Out-patient Clinic: Dr. Collier. 3.30 P.M., Lecture:—Dr. Kinnier Wilson: Old and New Afferent Systems.

Tuesday, Feb. 8th.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Lecture:—Dr. Collier: Diagnosis of Cerebral Vascular Lesions.

Thursday, Feb. 10th.—2 P.M., Out-patient Clinic: Dr. Farquhar Buzzard. 3.30 P.M., Lecture:—Dr. Farquhar Buzzard: Neuritic Affections of the Upper Limbs. (II.)

Friday, Feb. 11th.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Lecture:—Mr. Sargent: Cerebral Abscess.

Fee for Post-Graduate Course £7 7s. C. M. Hinds Howell, Dean.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

Thursday, Feb. 10th.—4 P.M., Lecture:—Dr. Nabarro: Congenital Syphilis.

MIDDLESEX HOSPITAL MEDICAL SCHOOL (University of London).

Tuesday, Feb. 8th.—3 P.M., Emeritus Lecture:—Surg.-Rear-Admiral Bassett-Smith: Trypanosomiasis.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westmoreland-street, W.

Monday, Feb. 7th.—5.30 P.M., Post-Graduate Lecture:—Dr. F. W. Price: The Arterial Pulse.

ST. MARYLEBONE GENERAL DISPENSARY, 77, Welbeck-street, Cavendish-square, W.

Post-Graduate Course on Infant and Child Welfare.

Tuesday, Feb. 8th.—10.30 A.M., Dr. E. Pritchard: Practical *Demonstrations on the Management and Feeding of Infants and Young Children—Demonstration VII., The Uses of Dried Milk and Patent Foods.*

Thursday.—3 P.M., *Demonstration VIII., The Management of Difficult Cases.*

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, 49, Leicester-square, W.C.

Thursday, Feb. 10th.—6 P.M., Chesterfield Lecture:—Dr. W. K. Sibley: Alopecia and its Treatment.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

Tuesday, Feb. 8th.—4.30 P.M., Lecture:—Dr. H. R. Dean: Recent Work on the Pneumococcus and the Serum Treatment of Pneumonia.

SALFORD ROYAL HOSPITAL and ANCOATS HOSPITAL POST-GRADUATE DEMONSTRATIONS, at the two Hospitals alternately.

Thursday, Feb. 10th.—4.30 P.M., Dr. Morrison: Radiographical Demonstration. (At Ancoats Hospital.)

ST. MARY'S HOSPITALS, MANCHESTER, POST-GRADUATE LECTURE, at Whitworth-street West Branch.

Friday, Feb. 11th.—4.30 P.M., Dr. F. Shaw: The Present Position of Cæsarean Section.

MANCHESTER BABIES' HOSPITAL.

Post-Graduate Lectures and Demonstrations in the Onward Buildings, Deansgate, or at the Hospital, Slade-lane.

Saturday, Feb. 12th.—3.30 P.M., Dr. Dyson: Skin Diseases in the *Infant.* (At Onward Buildings.)

MANCHESTER FRENCH HOSPITAL POST-GRADUATE LECTURES, 24, Acomb-street, Whitworth Park.

Thursday, Feb. 10th.—4.30 P.M., Dr. W. J. Leighton: Some Chronic Ear Diseases.

Notes, Short Comments, and Answers to Correspondents.

WARNING TO HOSPITAL AUTHORITIES.

WE are asked to draw the attention of all medical practitioners, and particularly of hospital authorities, to a woman calling herself Margaret Crawford, M.B., Ch.B. Leeds (or Margaret de Lancy Williams), whose arrest is sought on a warrant by the Metropolitan Police for alleged offences against the Medical Act, 1858. It is possible that this woman will seek admission to some hospital or infirmary for the purpose of obtaining instruction in midwifery, and it is requested that any information concerning her should be communicated at once to the local police.

PUBLIC HEALTH IN CALCUTTA, 1919.[1]

THE death-rate in Calcutta during 1918, calculated on the Census population of 1911, was 35 per 1000, representing what Dr. H. M. Crake, the medical officer of health, has characterised in his report as "the appalling total" of 31,371 deaths. A further considerable increase in mortality followed in 1919, when there were 37,839 deaths, giving a ratio of 42·2 per 1000; this is the highest death-rate ever recorded in the city, except that of the plague year, 1900, which was 53·7, and is in great contrast to the rate for 1917 (23·8), which was the lowest ever recorded, and to the quinquennial ratio (1914–18), which was 28·0 per 1007. If 2170 imported cases be deducted, the rate for 1919 becomes 39·8 per 1000. Cholera, small-pox, and influenza were all prevalent in an acutely epidemic form. There was, as usual, considerable variation within the city, which had (in 1911) a population of 896,067. Thus, in Jorabagan Ward the death ratio was 47.4, in Entally 51·3, and in Kidderpur 81·1. On the other hand, in Bamun Bustee the rate was only 26·5; in Fenwick Bazar, 25·2; and in Park-street, 15·3. (The death-rate for Greater London, in 1918, was 15·0 per 1000.) In Fort William the ratio was indeed only 5·8, the quinquennial average having been 3·6. There is evidently nothing in the climate of Calcutta to necessitate a mortality of 42, still less of 81, per 1000. In regard to social condition and religious faith, among Hindus (who compose the great majority of the population), the death-rate was 45·2; for Mohammedans, 37·9; and for Anglo-Indians and other non-Asiatics (numbering 27,659), it was 27·4. As has often been pointed out, the mortality among females was much higher than among males; the respective ratios, 53·7 and 36·7, were as 146 to 100. As Dr. Crake remarks, "this is one of the most striking features of the vital statistics of Calcutta. It has been observed ever since accurate records were kept, and will, I am afraid, continue for many years to come. The heavy mortality amongst females is, in my opinion, intimately associated with the purdah system ...... depriving women of fresh air, and constantly exposing them to insanitary environments." In Burra Bazar Ward, with a mortality of 34·2 per 1000, the rate for females was 63·2, and for males 28·2; there are 140 persons per acre, not so dense a population as in many other wards. In Bamun Bustee Ward, with a mortality of only 26·5, the female ratio was 62·5, and that for males 18·1; here the average density is only 24 per acre. Dr. Crake points out that this "high female death-rate in a first-class European residential quarter is startling, but on examining the data on which the rate is calculated, it is evident that a rate per 1000 based on 37 deaths occurring amongst a female population of 592 must be accepted with caution. In a precisely similar adjoining ward (Park-street) there were 20 deaths among 815 females, a rate of 24·5 per 1000." It is to be noted, however, that in the preceding quinquennium there was a similar great disparity between the sexes in Bamun Bustee, 32·0 deaths per 1000 among females, compared with 10·6 among males.

Principal Causes of Death.

With reference to the diseases that were the principal causes of death, an increase in prevalence has to be recorded in almost every case. For influenza (3863 deaths), however, there was a reduction (3·7 per 1000, compared with 4·6 in 1918), though many deaths from this cause may have been returned under respiratory diseases or fevers. There was some increase in plague, 334 deaths, or 0·37 per 1000 compared with 0·23 in 1918: in Alipur Ward there were 52 deaths (2·6 per 1000). Dr. Crake repeats his warning as to the existence of "many potential plague centres in Calcutta, and that the conditions in many parts of the city are still favourable to its propagation." Cholera caused 3688 deaths (4·1 per 1000), compared with 1526 deaths in 1918. The epidemic began in October, 1918, suddenly assumed an acute form in January (610 deaths), and again in April (1050 deaths), and came to an end in July. Cases occurred in every ward of the city. Kidderpur had the highest mortality (8·0 per 1000), but, with this exception, all the wards with a cholera death-rate of 5 per 1000, or more, abut on the river, pointing to the obvious cause. "The large amount of water-borne cholera in a city like Calcutta, with a filtered water-supply of remarkable purity, is a positive crime, but cannot be eradicated so long as ceremonial ablutions in Tolly's Nullah and contaminated tanks play a large part in the social and religious life of certain sections of the population." Nearly a hundred persons actually suffering from the disease, returning from a native festival at Saugor Island (at the mouth of the Hugli river), arrived in the city on Jan. 17th and 18th, no previous intimation having been received. Prompt action was taken, and everything possible done to deal with this emergency. 300 deaths from cholera occurred between Jan. 16th and 21st, 217 being among the pilgrims who had arrived from Saugor. Dr. Crake emphasises the necessity for systematic medical inspection of all boats arriving at Calcutta, also for a quarantine station and segregation camp. There was an outbreak of small-pox causing 1870 deaths (2·1 per 1000), a considerable increase over the three years immediately preceding, in which the ratios had been (1916–18), 0·06, 0·03, and 0·60 respectively. Primary vaccination is only compulsory at six months of age, therefore a high incidence among infants is almost inevitable: 712 deaths, however, occurred in children under 5 years old, regarding which Dr. Crake (in agreement with Kitasato) considers that the protection afforded by vaccination diminishes much more rapidly than was formerly held to be the case.

Enteric fever was more prevalent than in any of the five years immediately preceding, the death-ratio being 0·44 per 1000, compared with 0·38 in 1918, and 0·27, for the quinquennium 1914–18. The highest ratio (0·83 per 1000) occurred in Jorasanko Ward, with 227 persons to the acre, the most crowded ward (except one) in the whole city; but in other wards with a relatively high enteric incidence there was no obvious connexion with sanitary defects. Infection through carriers is considered to be probable. There was a very slight increase in tuberculosis (2·1 deaths per 1000, compared with 2·0 in 1918, and 1·7 in 1917). The highest incidence occurred in Jorasanko and Sukeas-street Wards (2·7 in each). For Hindus (2·2) and Mohammedans (2·1) the ratios were almost the same; and among Indian Christians the mortality (1·8) was much lower than in 1918, when it had been 4·8 per 1000. The female death-rate for this disease was 3·2, exactly double that for males (1·6); it is, as has been frequently pointed out, chiefly the young women who suffer; for the age-period 15 to 20 the death ratio was 5·6 for females, compared with 1·5 for males. This disparity is due to the purdah system, and continues, though in a lesser degree, up to the age of 40. There was less influenza than in 1918, the deaths (3363) amounting to 3·7 per 1000, compared with 4·6 in the previous year. Kidderpur Ward was most affected, with 12·9 deaths per 1000. The epidemic was dealt with on lines similar to those found to be satisfactory in 1918, over a hundred relief centres being opened for the treatment of mild cases, and serious cases being visited at their homes. A mysterious outbreak of epidemic dropsy occurred in the latter half of the year, causing 96 deaths (65 in November and December). Hindus suffered more than Mohammedans, and women more than men. A protozoal infection is suggested, the bed-bug acting as carrier. Many other subjects of interest are dealt with in this valuable report, which is fully illustrated with diagrams, tables, and a map of Calcutta.

MENTAL TESTS FOR SCHOOL CHILDREN.

FROM the eleventh annual report of the Manchester school medical officer (Dr. A. Brown Ritchie) for 1919, just issued, we learn that medical inspection is being carried out on pre-war lines, but that a larger staff may be needed. Only 40 children needed compulsory cleansing, as compared with 85 in the previous year and 413 in 1915. Of skin diseases 738 cases were discovered and 95 cases of ringworm. At the school clinics for minor ailments in 1915 25,000 cases were treated, as compared with 196,000 in 1919. Included in the report is a suggestive preliminary note by Dr. H. Herd, on the Use of Psychological Tests of Mental Retardation. One of the most important duties of the medical officer is the diagnosis of mental deficiency or backwardness, and the most important part of such an examination is that of the psychological characteristics of the child. It is most essential to examine the functioning mental processes of the child, and this can only be done by definite mental tests. Scholastic progress affords but a poor criterion of the real mental grade of the child. A child with many superficial signs of school "smartness" may be lacking markedly in higher thought qualities, while the innate intelligence of a child may be only partially patent during school work, and appearing only at a late stage of development. Several classes of tests are described, but these mental tests are necessarily only tests of intelligence, and the intelligence is not the whole man. "The instinctive emotional factor," says Dr. Ritchie, "enters as largely into our actions as those of intelligence. The place of the subconscious in life is only now beginning to be recognised, and the discovery is re-creating psychology. Intelligence tests therefore necessarily miss much, but for the immediate practical purpose of the certifying school medical officer their value is undoubted."

[1] Report of the Health Officer of Calcutta. Corporation Press, Calcutta, 1920.

THE CONTAMINATION OF SHELL-FISH.

THE Health Ministry has recently issued prohibitory orders against the mussels at Lympstone, and promised to provide proper tanks for the purifying of the fish. At the last meeting of the Exeter Port Sanitary Authority it was stated that communications had been received from Dewsbury and other midland towns reporting that the mussels had been sent to them; these were proved on bacteriological examination to be contaminated, and that cases of illness had been caused by the fish. The authority decided to inquire why the mussels had been sent away contrary to regulations. It was also determined to write to the Ministry of Health requesting that the work of constructing the purifying tanks should be expedited.

SLUM LIFE IN MANCHESTER AND ITS RESULTS.

IT is stated that there are 150,000 persons living in slum property in certain already overcrowded areas of Manchester —that is, in Hulme, Ancoats, and Deansgate. Many families are crowded into the 20,000 houses which, according to medical standards, are unfit for human habitation. Even if the health authorities turned these people out of these vastly unhygienic "houses," so great is the shortage of accessible habitations that the outcasts would have no roof to shelter them. In some of what are called "two-up and two-down" tenements, three, four, or five families are huddled together, so that it is impossible to ensure the proper separation of the sexes. Naturally, the death-rate in these over-congested slum areas is abnormally high, varying from 23-29 per 1000, as against 14·5, the general death-rate for the city; the infant mortality is 191·6, as against the general rate of 111·2 per 1000. In one of these areas the death-rate for phthisis is 6, as against 1·56 for the whole city. Moreover, it would seem that house shortage and other conditions lead to the widespread adoption of a policy of birth control by young married couples.

EARLY SEX EXPERIENCE.

Dr. W. A. Brend's article on Psychotherapy and War Experience in the January issue of the *Edinburgh Review* is a useful outline in non-technical language of the new psychology in which Freudian teaching has taken its proper place. Speaking of the early age at which sex tendencies appear, and the help which parents might give in preventing abnormal developments, Dr. Brend goes on to say:—

> "Among boys much harm is done by parents and teachers in stigmatising certain tendencies and actions as vicious and shameful. It is now recognised that these tendencies form one of the natural stages on the way up to full sexual development. The physical harm is probably immaterial; the psychic harm which may result from creating a feeling of guiltiness and inferiority in the boy, or dread of consequences, may be great and lead to life-long disaster."

This statement of Dr. Brend as it stands, seems to us one of those one-sided pronouncements containing only a half truth, which may do as much harm as good. Certainly the harm which comes from masturbation has been exaggerated, and to try to keep boys straight by frightening them is almost always criminal. But to suggest that masturbation (and, presumably, the other practices that often go with it) does not matter is nonsense, as anyone knows who has seen the sequelæ in some boys or who remembers the social value of a normal sex outlook.

In regard to the prevalence of masturbation under a system of co-education, the head of a large mixed residential school writes:

> "Of course, here, as everywhere where adolescents are together, it is not unknown. But I am quite sure that it is not the normal accompaniment of sex-development here. Public opinion is against it. Heads of dormitories, if they have reason to think that any of those in their room are falling into it, speak to them or ask me to do so. That is no more than is done in many schools; the one point in which co-education seems to me to be of special help in the matter is that the daily intercourse of boy and girl affords a constant, largely unconscious, satisfaction of the awakening sex instinct, and so keeps it from turning in upon itself and from that brooding upon it that is, I am sure, the cause of most of the tendency to masturbation."

Plenty of interests—emotional outlet in art, and daily intercourse of the sexes—are undoubtedly useful means of keeping sex-development free from the need of this practice as a rmal stage, and when it is present of making it a com- tively brief stage that does not get the lasting hold that is mind as well as body.

MATERNAL PRECAUTIONS OF THE ELECTRIC SKATE.

Mons. Raphael Dubois made an interesting report to the Académie des Sciences at its session on Dec. 27th, 1920. A large electric skate (*Torpedo mormorotae*) was brought to the Maritime Laboratory of Physiology at Tamaris-sur-Mer. It was on the point of bearing young and gave strong electric shocks. These, apparently, had no ill-effects on the young, who were born the same night and were found snugly concealed beneath their mother next morning. The latter could be handled without any shock while the young were near her, but when the young had been taken away for experimental purposes powerful electric shocks reappeared. Mons. Dubois concludes that the electric discharge is not purely reflex but can be controlled, since in this case it was withheld to avoid doing damage to the offspring.

CHLOROPICRIN AS INSECTICIDE.

EXPERIMENTS carried out with chloropicrin in France have shown that this poison gas is a very effective weapon when used against vermin and insects. No other method, it is claimed in the *Archives de Méd. et Pharm. Navales* (December, 1920, p. 448), is so successful in ridding a building of fleas. A quantity of chloropicrin corresponding to 5 g. per cub.m. is placed in each room to be disinfected, and in a few hours every flea is dead—in carpets, furs, clothing, or no matter where else they may have installed themselves. The gas has no action on metals, paints, or dyes, and all fumes are removed by a few minutes' ventilation. Dr. Mirguet of the French Navy considers this method as particularly convenient for the destruction of vermin and insects on board ship, and urges its routine adoption by the French Ministry of Marine both on account of its intrinsic virtues and on the grounds of economy. The estimated cost is 13–14 francs per litre.

A RECORD OF
SEVENTY-SIX CASES OF
UTERINE FIBROIDS AND CHRONIC METRITIS TREATED BY X RAYS.

A Communication to the Section of Obstetrics and Gynæcology of the Royal Society of Medicine on Feb. 3rd, 1921,

BY T. WATTS EDEN, M.D. EDIN., F.R.C.P. LOND., F.R.C.S. EDIN.,
OBSTETRIC PHYSICIAN, CHARING CROSS HOSPITAL; SURGEON TO IN-PATIENTS, CHELSEA HOSPITAL FOR WOMEN;
AND
F. LIONEL PROVIS, M.R.C.P. EDIN., F.R.C.S. EDIN.,
SURGEON, CHELSEA HOSPITAL FOR WOMEN; GYNÆCOLOGIST TO THE ITALIAN HOSPITAL, ETC.

THIS paper is a record of 46 cases of uterine fibroid tumours and 30 cases of chronic metritis treated by us with X rays during the years 1914 to 1920 inclusive. All the cases were under the personal supervision of one or other of us throughout treatment, and the X ray exposures were in every case made by one of us (F. L. P.). A large proportion of the cases were patients seen in private practice. Three have died from independent causes since treatment, and we have been able to obtain reports as to the present condition of all but 14 cases, at intervals varying from three months to six years after the treatment. A brief epitome of each will be given later on in the paper. Of the 46 cases of fibroid tumour 30 were married, 15 were single; of the 30 cases of chronic metritis 25 were married, 5 were single. With regard to age, it may be said that 8 cases were between 36 and 39 inclusive, the remainder from 40–56 inclusive; the proportion of cases below 40 was therefore small—viz., about 10 per cent.

Selection of Cases.

The first point to which we wish to direct attention is the method of selection for X ray treatment. Not all cases are suitable for this treatment, and at first we had to feel our way with some caution. The points which bear upon selection are: (1) age of patient, (2) size of tumour (if a fibroid), (3) character of hæmorrhage, (4) degree of anæmia, (5) presence of complications, such as inflammatory disease of the appendages, degeneration of a fibroid tumour, &c.

(1) *Age.*—We have rarely (in only eight cases) treated patients under 38 years of age with X rays; the effect of the rays is exerted primarily upon the ovaries, resulting in destruction, more or less complete, of the active ovarian tissues. Preservation of the ovarian secretion in women under 38 is of great importance, but as the age of the climacteric approaches its importance becomes less.

(2) *Fibroids.*—Fibroid tumours which exceed the level of the umbilicus in height we have, generally speaking, rejected. Nearly all fibroids shrink materially in size after exposure to X rays, but the shrinkage of large tumours may not be sufficient to relieve mechanical symptoms. We have found that while, in such cases, it may be practicable to induce complete amenorrhœa, the tumour may cause so much discomfort from its bulk that only partial relief of symptoms is obtained.

(3) *Hæmorrhage.*—The character of the hæmorrhage is important when it raises the suspicion of malignancy. If the type of menorrhagia is not maintained, and irregular or interval-bleeding is present, the uterus should be first explored to exclude carcinoma of the body.

(4) *Anæmia.*—As will appear later, the first treatment, or the first and second treatments, may be followed by increased, and even by much increased bleeding. In the case of a patient profoundly exsanguine from repeated hæmorrhages it is therefore preferable to advise hysterectomy (vide Case 75).

(5) *Complications.*—Only simple and uncomplicated cases are suitable for X rays. A careful examination of the cervix was made in every case, to exclude appearances suggestive of a malignant growth. The presence of pain is a symptom which requires careful investigation; tenderness or rapid increase in size of a fibroid suggest degenerative changes; limitation of mobility or the presence of a tender swelling on either side of the uterus, or on both sides, suggests inflammatory disease of the appendages. Any of these conditions, if present, render the case unsuitable.

It will therefore be evident that we have not used X rays as a general substitute for hysterectomy, but have, on the contrary, limited its application to carefully selected conditions; and the cases treated have, in fact, constituted only a small proportion of the cases of fibroid tumours and of chronic metritis which have come under our notice in the period under review. We hold strongly that the indiscriminate treatment of these conditions by X rays is a mistake; every case so treated should first be passed as suitable by a competent authority.

With regard to the cases classed as "chronic metritis," it must be said that in every instance the diagnosis was clinical only; if no marked enlargement or irregularity in outline of the uterus could be made out the local condition was for convenience labelled "chronic metritis." In many of the cases the diagnosis was supported by the fact that curetting had been previously performed without relief.

Technique.

The technique adopted in the majority of cases was a modification of that used in Krönig's clinic at Freiburg, the principle of which is the administration of massive doses of X rays in the shortest possible time commensurate with safety as regards the skin of the areas irradiated. In a few cases the total dose has been reduced by diminishing the number of areas irradiated at each treatment, and it is noteworthy that the cases so treated comprise the greater proportion of the failures in our series. They frequently showed a recurrence of hæmorrhage after a period varying in duration, of amenorrhœa. These two facts support the conclusion we have come to from our experience—namely, the importance of giving massive doses and the administration of the treatment for one or two sittings after amenorrhœa has been induced.

In describing the technique it is not intended to go into the details of the technical side of the running of an X ray tube. This part of the technique requires special knowledge, and a lengthy description of the various apparatus used in the successful manipulation of an X ray tube for deep-seated therapeutic purposes. We will therefore only deal with that part of the technique with which the clinician of to-day should be conversant.

The tubes used have been of the water-cooled variety, equipped with osmo regulators, by means of which the hardness of the tube can be regulated. They are maintained at a hardness of 8 to 9 Bauer with an equivalent spark-gap of 8 to 9 inches, with the passage of 2 to 3 milliampères through the tube circuit. The rays are filtered through a 3 mm. aluminium filter, which cuts off all but the hardest rays emitted from the tube. Further filtration is provided by placing between the aluminium filter and the part to be irradiated a loofah sponge enclosed in chamois leather, together with four layers of satrap paper, all of which are enclosed within a linen bag. These measures seem adequately to protect the skin from any injurious effects. The tube is fixed in a suitable stand, the box of which can be moved up and down and fixed at any required angle by manipulation. A wire connects the tube-stand to the earth.

The patient is placed on a suitable couch and the lower abdomen from the level of the umbilicus laid bare. Over this area eight or six square areas are marked out with a coloured pencil, which constitute eight or six ports of entry for the irradiations. Each area is irradiated separately, and is enclosed by two lead angles which are so placed that only the field to be irradiated is left exposed. Over that area is placed the linen bag containing the loofah sponge, chamois leather, &c., already mentioned. On the top of this is placed a sheet of lead rubber in which is cut a square window, and through this the rays pass to the exposed area of the abdomen. In the centre of this square area resting on the linen bag is placed a Kienböck photographic paper, a strip of bromide of silver paper, which when developed acts as a rough guide to the amount of X rays administered. The tube is now placed in position, the tube-box being adjusted in such a manner that the anticathode of the tube is in line with the centre of the square of the exposed area, and at such an angle that the rays pass down into the pelvis. Each area is irradiated for ten minutes.

This concludes the treatment given on the first day, for the remainder of which the patient is ordered to bed. On the following day, with the patient lying prone, four areas are marked out over the sacral and sacro-iliac regions, and each irradiated for ten minutes. The same protective measures, &c., are used as those described when irradiating the abdominal areas. Each "treatment" comprising the exposures on the two consecutive days lasts some three to four hours and comprises one attendance on two consecutive days, the abdominal areas being irradiated on the first day and the sacral areas on the second day. The patient is ordered to bed after the treatment on the first day, but this is not necessary in the majority of cases following the sacral exposures.

An interval of three weeks is allowed to elapse between each treatment as a precautionary measure against injury to the skin. The time selected for administering the treatment should be shortly after the termination of a period. If given immediately before the onset of menstruation it is likely to increase the hæmorrhage rather than to diminish it, especially in the early treatments. The requisite number of treatments will be found to be from four to six, and one treatment at least should be given after amenorrhœa has been induced. Many factors, however, have a bearing on the number of treatments required, and in certain cases a modification of the technique here described may be advantageously adopted.

Dosage.

We now come to the important consideration of the estimation of dosage.

It will have been observed in the summary of the cases no mention of dosage has been made, but that in its place the total time exposure of each case has been given. The reason for this is that none of the many methods devised for the estimation of dosage possess even approximate accuracy. The so-called dosage each area is to receive must in the present state of knowledge and with the existing methods used in estimating the same be left to the judgment of the operator. He will give to the patient that amount of X rays that he knows can be given with safety, gauged by the characteristics of the tube and the number of milliampères passing through it, the reading on the Bauer qualimeter and the length of the equivalent spark gap, controlled by one of the methods devised for estimating the dosage through the discoloration of pastilles or photographic paper after it has been developed. In other words, given certain working data the operator knows for what length of time he can submit his patient to irradiation without inflicting any damage; but to say he can administer such and such a dose of X rays to each ovary is not practicable. Much work has been done, and is being carried out at the present time, to devise some means of recording the accurate dose of X rays administered, but the difficulties of this problem are very great, and until we have some fairly accurate method of measuring the dose the patient receives it appears to us a wiser plan not to speak of some imaginary dose the patient is supposed to have received, but to express the dosage in terms of time exposure.

Effects of X Ray Treatment.

We now come to describe the effects of the treatment as we have seen them in our series of cases.

Mode of action.—It will be sufficient to remember that the outstanding effect of the rays is exerted upon the ovaries, leading to destruction of the follicular and interstitial elements, and eventually to complete fibrosis of the organ. At the same time a very marked and rapid shrinkage occurs, as a rule, in the fibroid tumour, up to complete disappearance in some instances. The tissue elements of the tumour are certainly absorbed, and we believe that this must be due to some process analogous to autolysis. It may be that under the influence of X ray irradiation ferments are produced locally which are active as against the elements of the tumour, but inert as against those of the normal tissues. Inasmuch as the operation of double oöphorectomy for fibroids as formerly practised seldom resulted in any marked degree of shrinkage of the tumour, it is reasonable to conclude that this reduction in size of the fibroid is largely due to the rays, not to the elimination of the internal ovarian secretion.

Effect on menstruation.—We have succeeded in all but five cases treated by X rays either in inducing complete amenorrhœa or in so reducing the frequency and the severity of the losses as to relieve symptoms completely. The dose required, as estimated by the time exposure, varied very much, the limits being 2 hours 27 minutes and 15 hours 35 minutes. The longest exposures (those over 10 hours) were all given in cases of fibroid tumours; on an average it may be said that cases of chronic metritis require a smaller dose to produce amenorrhœa than do fibroids. We cannot find in our cases that the age of the patient has any bearing upon e dose required, although we anticipated in starting our rk that the younger ones would require the larger doses.

The initial effect upon menstruation is often to increase the amount of the flow. This often occurred after the first or second treatment. On the other hand, the first exposure is sometimes followed at once by marked diminution of bleeding, shown by absence of clots, or by a prolonged intermenstrual interval. The early increase in menstrual losses is probably brought about by a stimulation of the activity of the ovarian tissue representing the first effect of a small dose of the rays. As the effects of the rays are continued, stimulation of ovarian tissue is replaced by a reverse action which ends in complete destruction. In the case of fibroid tumours we have several times noted the occurrence of a slight, continuous, blood-stained discharge for some weeks after menstruation proper had ceased. This is probably associated with the changes in the tumour which result in shrinkage.

There were in all 10 cases in which we did not succeed in inducing complete amenorrhœa—5 fibroids and 5 chronic metritis. In 3 of the 10 cases the losses continued to be severe and the patients were eventually operated upon. The details (Nos. 8, 12, and 76) will be found in the account of selected cases at the end of this paper. Another patient (No. 41) refused to continue the treatment, which, if persisted in, would probably have been successful. In another case (No. 29) the treatment, although thoroughly tried, also failed to reduce the monthly losses except temporarily. This patient still refuses operation, and her case must also be classed as a failure. If No. 41 be eliminated there remain 4 cases out of 76—i.e., 5¼ per cent.—in which we failed to produce any lasting effect upon menstruation. All four were cases of fibroid tumour, and accordingly the percentage of failure in cases of fibroid tumour works out at 8·7 per cent., while in cases of chronic metritis there was no failure at all.

Cases in which menstruation was controlled but not suppressed.—In 5 cases a very interesting result was obtained, for, without suppressing menstruation altogether, the treatment so far controlled it that symptoms were entirely relieved without actually inducing the menopause. These cases are numbered 39, 49, 56, 65, and 70; the first a fibroid, the others chronic metritis. A typical example of this class is case No. 39, a patient, 45 years of age, with a fibroid tumour extending nearly to the umbilicus. After prolonged treatment she still has a moderate period about twice a year, there are no menopause symptoms, her general health is good, and the tumour is about two-thirds of its size before treatment. The most striking example of all is No. 70. This was a patient aged 40, classed as chronic metritis, with a history of menorrhagia for 2½ years before treatment. After five treatments she had four months amenorrhœa; then the periods returned, normal in amount and duration. She has continued to menstruate normally for four years and nine months—i.e., up to December, 1920—the date of the last report.

Such effects as these are probably to be explained by assuming that a varying resistance is offered to the rays by ovarian and uterine tissues. The active ovarian elements may perhaps be put out of action by the rays for a more or less prolonged period and then recover some of their functional potency, or the destruction of these elements by the rays may be incomplete, sufficient follicular tissue escaping to induce occasional menstrual periods. Or again, changes may be induced in the uterus which tend to control menstrual hæmorrhages.

Partial suppression of menstruation is not to be regarded as a failure. It would perhaps be right to regard the ideal dose of X rays as that which suffices to confine the monthly losses within normal limits, rather than that which suppresses them altogether. In the present state of uncertainty as to the estimation of dosage the attainment of such an ideal seems impracticable, but our experience leads us to believe that by careful graduation of time-exposures we may be able to reduce excessive monthly losses, or to induce partial amenorrhœa, with the same degree of certainty as we can now induce complete amenorrhœa.

General Effects of X Rays.

The immediate effects produced by the prolonged exposures we used were not constant. The majority of our patients suffered more or less from fatigue, which lasted for two days or more, and which led us to advise that after the X ray exposure the patient should go to bed for the remainder of the day. In one or two rather marked prostrations occurred. In a few instances, on the other hand, the rays appeared to produce a stimulating effect, the patient feeling all the better for it.

Local Effects.

Skin.—The areas exposed to the rays always show immediately afterwards a more or less marked flush, which is later replaced by brown discoloration or pigmentation. No soreness or irritation occurs in connexion with this change, and after treatment has ceased the pigmentation very gradually disappears. In three cases a mild dermatitis occurred during treatment, which was in consequence interrupted for a time. There was no loss of tissue and very little pain accompanying it; in the worst of the three treatment was suspended for six weeks and was then resumed without any further trouble. We have had no case in which skin trouble has developed subsequent to treatment.

The uterus in chronic metritis.—Our impression from bimanual examination made at varying intervals after suppression of menstruation is that a definite reduction in size occurs in the uterus coincident with the suppression of menstruation.

Fibroid tumours.—Definite shrinkage of the tumour followed the suppression of menstruation in all of our fibroids treated except four. The shrinkage is fairly rapid and can be followed during the treatment. In three instances we have noted the practically complete disappearance of a small fibroid tumour, the size of a three months gravid uterus, in less than a year. By "practically complete disappearance" it is meant that nothing remained except one or two small surface nodules suggestive of subperitoneal fibroids, the uterine body being otherwise of approximately normal size. The majority of the cases in which this marked shrinkage has occurred have been examples of small tumours not exceeding the size of a 3½ to 4 months gravid uterus. In three cases, however, we have seen a fibroid reaching as high as the umbilicus disappear entirely with the exception of one or two nodules (Cases 23, 31, and 38). The maximum shrinkage appears to take place in from 6–12 months in tumours not exceeding the size of a 3–4 months pregnancy, and in from 12–24 months in tumours larger than this.

Pelvic and abdominal viscera.—In addition to the effects described upon the uterus and the ovaries, we have been unable to detect any influence upon the other pelvic viscera except possibly in one case recorded fully below. (Case 59.) We have paid careful attention to the mobility of the pelvic organs before and after treatment, and except in this doubtful case we have never found after the X ray treatment that any tenderness or loss of mobility was manifested, in fact, nothing whatever to suggest that any local inflammatory changes were induced by the X rays. In a few cases nausea was complained of for one or two days after each treatment; in one case (Case 1) nausea was very severe and lasted for several days after each treatment, during which the patient could take no food. On one occasion the same patient suffered from severe diarrhœa after a treatment. For over two years since then she has been in good health and is habitually constipated. Whether these effects should be attributed to a direct action of the rays on small intestine or other viscera we are unable to say. In two or three of our cases a little looseness of the bowels was noticed for a few days after treatment.

Possible Risks of Injury by X Rays.

This leads us to the question, Is there any risk that injury may be done by X rays to the skin or to the pelvic and abdominal viscera? With regard to the skin, we have had two cases only of slight dermatitis, both of which cleared up without ulceration; there is no doubt that by efficient filtration and protection the skin can be adequately guarded. The question of the possibility of injury to such organs as the intestines cannot be so readily answered, as they are not under direct observation. Cases of X ray ulceration of the small intestine have been recorded in France and Germany, and in view of the frequency with which coils of jejunum are found lying in the pelvis they may, of course, be subject to irradiation along with the other pelvic contents. No such case has occurred in our series, but we have had one case which was operated on for pelvic inflammation eight months after the cessation of treatment, and terminated fatally. We believe the condition was in reality due to an acute ascending infection which arose after the X ray treatment was concluded. Definite proof is, however, wanting; we therefore lay the facts of this case before the Section, as this is the only one in our series in which any suspicion could arise that injury had been caused by the X ray treatment.

CASE 59.—Married, aged 43; children, 3. (1/4/14.) Symptoms: Menorrhagia of two years' duration. Local conditions: Chronic metritis, uterus enlarged; mobility of uterus impaired; no evidence of tubal inflammation.

Treatment: Total exposure 5 hours 20 minutes in five treatments. April to July, 1914.

Effects on menstruation: Complete amenorrhœa from June, 1914. General effects: General health improved, but symptoms of intestinal irritation commenced with diarrhœa and some abdominal pain. (September, 1914.) These symptoms continued and the patient was admitted to Chelsea Hospital for Women in March, 1915, eight months after the last X ray treatment, not having been seen by me (F. L. P.) since the previous September. She was then found (per vaginam) to have a tender mass filling Douglas's pouch and extending into both sides of the pelvis, especially the left. The motions were fluid, containing small amounts of fæcal matter, but no mucus or blood, attacks of constipation and diarrhœa alternating.

March 23rd, 1915: Laparotomy performed. An inflammatory swelling was found filling up the pelvis, shut off from general abdominal cavity by adhesion of bowel and omentum, which were separated. Uterus adherent to rectum; both tubes inflamed, the left containing about a teaspoonful of pus. On separating uterus from rectum pus escaped which was loculated between the two organs. An opening was at this stage discovered in the rectal wall; whether it was caused by separating adhesions or whether it was an old opening communicating with an abscess cavity could not be decided. There was a great deal of perirectal inflammation. The left tube was removed. The hole in the bowel was closed with great difficulty and the uterus lightly sewn over it. A gauze drain was inserted and the abdomen closed. By an incision in the left inguinal region a portion of the descending colon was brought out of the abdominal cavity and a roll of gauze pushed through the mesentery to secure it in position, and a few stitches fixed the bowel to the inguinal incision. The colotomy was performed four days later. At this time a fæcal fistula had formed in the subumbilical incision. The patient was at first very ill; 48 hours after operation she was much improved, but her condition soon gave rise to considerable anxiety, chiefly because of the quantity of pus discharged from both wounds.

May 5th, 1915: Patient passed a large quantity of pus per rectum. From this date to 5/8/15 condition improved, though the state of the abdominal wounds was never satisfactory. At the latter date severe diarrhœa set in from which she recovered, and her general condition began to improve again, her temperature falling, and her general aspect was much brighter. On 13/8/15 patient was seized with sudden abdominal pain, a large quantity of pus exuded from the colotomy wound, and she died with all the signs of general peritonitis.

This case has been reported fully on account of its importance. The question arises, Was the pelvic condition due to X ray treatment? Unfortunately, no post-mortem examination was made and the presence of ulceration of the bowel cannot therefore be excluded. The first symptoms, sharp pain and flatulence after eating, which also caused the bowels to act slightly, commenced six weeks after the last treatment; the bowels were moved in these attacks some 10 to 12 times and the condition was always relieved by a small dose of castor-oil. This condition, gradually getting worse, continued till her admission to hospital, but the patient was not seen after January, 1915, till her admission in March, 1915.

The fact that both tubes were inflamed points to the possibility of a recently acquired ascending infection, or it may be that a pre-existing but undetected tubal inflammation was activated by the X ray treatment. The early symptoms, which commenced six weeks after the last X ray treatment, pointed, however, to intestinal irritation, and this is the only point in the case which cannot satisfactorily be explained.

The X Ray Menopause.

We have taken the symptom of "flushings" as the best available guide to the severity of the menopausal effects, and inquiry has been made upon this head in every case. The result is that in a little less than 50 per cent. of our cases "flushings" have been reported as "slight" or "absent," or the inquiry has not been answered; in one-eighth they were reported as moderate, and in three-eighths as "severe." In many of the latter class the flushings were frequent both day and night, and persisted in some for two years and upwards after the treatment had ceased. We formed the impression that in some of our cases, a small proportion of the whole, this symptom was more severe and prolonged than we have ever seen it in the natural climacteric.

In all other respects there is nothing that calls for comment in the menopause, except that nervous symptoms of a functional character appeared to be less frequent than under natural conditions. Many of our patients have inquired of us whether as a result of the treatment they would grow fat or lose their feminine qualities of body and mind. Special inquiry has been made of all our patients with regard to the former, with the result that though the majority have gained a certain amount of weight there has been no tendency to corpulence of an unsightly character. With regard to the latter, we have made inquiry when opportunity offered and have not found a single instance in which signs of masculinity appeared or in which there was any loss of sexual feeling; in one case there was a distinct increase of sexual feeling during the treatment, in all others the inquiry was negative.

Relative Advantages of X Ray Treatment and Operation.

As X ray treatment is only suitable for carefully selected cases, we do not think that it will ever supplant hysterectomy as the chief method of dealing with cases of uncontrollable uterine hæmorrhage. Generally speaking, all cases of chronic metritis or fibroid tumours which are complicated by inflammatory disease of the adnexa, all cases of large or degenerating fibroid tumours, and all cases of fibroid polypus must be dealt with by operation. The same must be said of all cases in which malignant disease cannot be satisfactorily excluded. At present it must also be said that only women of 38 years and upwards are suitable for X ray treatment.

These contraindications being granted, there still remains a considerable number of cases of uncomplicated chronic metritis and of small fibroid tumours which can be satisfactorily dealt with by X rays. It is, in our opinion, probable that further experience of the treatment, and perhaps improved technique, will enlarge the scope of the method beyond the limits which we have defined for it. It follows that we have an alternative to hysterectomy in this group of cases, and it is as an alternative procedure only that we have come to regard it.

To many women an operation is an ordeal which is greatly dreaded, while others submit to it with very little reluctance. Most of the cases which we have treated have in fact been so treated on account of the great dread of an operation which these women have manifested. In certain others, special conditions which increase operative risks, such as Graves's disease or valvular disease of the heart, have been present. As a rule, in cases suitable for X ray treatment, we may allow the patient to decide whether she will be operated upon or whether she will be treated, unless some complication exists which will increase operative risks. Except when organic disease exists elsewhere which renders an operation more than ordinarily risky, if the patient prefers an operation she need not be dissuaded from submitting to it.

As compared with hysterectomy X ray treatment has the advantages that the ordinary life and work of the patient need not be interrupted for more than two days at a time, and that the prolonged partial invalidism, which often lasts for several months after an abdominal operation, is completely avoided. These are considerations to which we are bound to give weight, and which will in many cases influence the choice of method. The disadvantages of X ray treatment are the uncertainty as to the length of time required to produce the result aimed at, and the very slight risk there may be that the treatment will be unsuccessful, and that operation may eventually be required. The latter is a minimal risk, and will no doubt be eliminated entirely as experience grows.

Conclusions.

1. In our opinion X ray treatment should be regarded as the method of choice in women over 38 for all uncomplicated cases of severe hæmorrhage due to chronic metritis, or other conditions in which no neoplasm is present. In our experience these cases yield more readily to the treatment than do fibroid tumours. The presence of inflammatory disease of the tubes and ovaries is a contra-indication.

2. Fibroids of the size not exceeding the height of the umbilicus may be treated with X rays if the patient is over 38 years old, if the hæmorrhage is of the regular monthly type, and if there is no evidence of inflammatory disease of the tubes and ovaries, or of advanced degenerative changes in the tumour. If intercurrent conditions which tend to increase operative risks are present X ray treatment should be regarded as the method of choice, in other cases the choice may usually be left to the patient.

3. No case should be submitted to X ray treatment without a careful gynæcological examination being previously made, to exclude malignant disease, inflammatory complications, and degenerative changes in fibroids.

4. The risks of failure with X ray treatment in suitably selected cases are so small as to be negligible; the X ray menopause may be attended by more severe flushings than in the normal menopause, but in other respects there is no difference between them; there is no tendency to corpulency or to psychological changes.

SELECTION FROM EPITOME OF CASES.

The following cases, to which reference was made in the foregoing text, have been selected from an epitomised account of 76 cases:—

CASE 1.—Married, aged 48; children, 0; miscarriage, 0; March, 1918. Symptoms: Severe menorrhagia and dysmenorrhœa. Bad general health; frequent attacks of faintness; these were attributed by Sir James Mackenzie to anæmia resulting from excessive menstrual losses. Local condition: Uterine fibroid size of 2½ months pregnancy.

Treatment: Total exposure, 7 hr. 12 min. in four treatments, from March to June, 1918.

General effects: Patient suffered severely from nausea for several days after each treatment, and on one occasion there was severe diarrhœa. Period April 14th to 25th, much less in amount and less painful. Flushings began in May.

Last report, November, 1920: Complete amenorrhœa since April, 1918. Occasional slight brownish discharge for a day or two. Flushings were severe and still continue. Writes that she is "a new woman since the treatment."

CASE 8.—Married; aged 52; children, 1; miscarriage, 1; July 9th, 1916. Symptoms: Menorrhagia; very severe floodings following first confinement 28 years ago; severe dysmenorrhœa. Diagnosis: Chronic metritis. Uterus nearly twice its normal size.

Treatment: Total exposure, 3 hr. 15 min. in four treatments. July to October, 1918.

Effect on menstruation: Amenorrhœa for 6 weeks after first treatment. After this menses every 2 to 3 weeks, with very severe floodings, for which patient had to be plugged.

Hysterectomy was advised and performed Nov. 6th, 1918. At the operation no adhesions were found; uterus was twice its normal size, the condition present being one of chronic metritis with great thickening of the endometrium. Patient has continued well to the present date—January, 1921,

CASE 12.—Married; aged 37; children, 1; August 21st, 1916. Symptoms: Menorrhagia; very severe backache. Patient suffers from gastric ulcer. Diagnosis: Fibromyoma, extending up to 2 inches below the umbilicus.

Treatment: Total exposures, 3 hr. 29 min. Last treatment, Dec. 2nd, 1915. The treatment carried out by irradiating 3 to 4 areas every three weeks instead of 10 to 12 as was usually done, which probably explains the failure to produce permanent amenorrhœa. The patient refused to have further X ray treatment and requested that the uterus should be removed.

Effect on menstruation: Amenorrhœa, December, 1915, to June 24th, 1916, when a normal period occurred. Then missed for three months, when period came on and recurred every 14 or 21 days, with occasional floodings, to time of operation—March, 1917. Severe backache unrelieved by the treatment. Local effects: Tumour gradually diminished in size till August 3rd, 1916, when a subperitoneal fibroid the size of a hen's egg extending out from the right side of the uterus was all that could be found. General effects: General health improved. Flushings fairly severe still—Jan. 8th, 1921.

Operation (April, 1917): Supravaginal hysterectomy was performed; the uterus contained a fibroid, the size of which is not mentioned in the notes. There were dense adhesions between the uterus and the rectum, and some adhesions of small bowel to the uterus also. The left ovary was cystic. The right small and fibrotic. The left tube and ovary were removed with the uterus. Patient reports herself very well at the present time (January, 1921). No intestinal symptoms reported either before or since operation. The backache, however, remains severe. We consider that failure in this case was due to insufficient treatment.

CASE 23.—Married; aged 50; children, 4; miscarriage, 1; June, 1914. Symptoms: Severe menorrhagia for five years, 10/25. Suffered much from "heart trouble," and this was attributed by Sir James Mackenzie to the profuse monthly losses. Local conditions: Irregular fibroid tumour size of about four months gravid uterus.

Treatment: Total exposure 6 hr. 54 min. in four treatments.

General effects: Complete amenorrhœa after third treatment; first two treatments produced no diminution of bleeding. Severe flushings which lasted for about two years. Local effects: Complete disappearance of the fibroid was noted on March 17th, 1915, the uterus being approximately normal in size and outline.

Last report, January, 1921: No return of periods. General health excellent, and she leads a very active life. The uterus is now about the size of the normal nulliparous organ, and no trace of fibroid tumour can be found.

CASE 29.—Married; aged 42; children, 5; Jan. 8th, 1917. Symptoms: Severe menorrhagia, 10/24, bleeding being at times alarming in severity. Local conditions: Large nodular multiple fibroid tumour extending nearly to umbilicus in mid-line. Patient corpulent.

Treatment: Total exposure, 21 hr. 30 min. in 11 treatments over a period of 14 months.

General effects: The treatment completely failed to arrest bleeding; an interval of 5 months occurred at one time during treatment, but this was succeeded by irregular hæmorrhage which was still continuing, though in less quantity, in December, 1920. The patient persistently refused operation.

CASE 31.—Married; aged 46; children, 2; Oct. 2nd, 1917. Symptoms: Severe menorrhagia, 7-10/21. Local conditions: Smooth hard fibroid extending to lower border of umbilicus and with little mobility.

Treatment: Total exposure, 8 hr. 7 min. in six treatments, October 1917, to April, 1918.

General effects: No serious loss after second treatment; nearly constant slight show of blood from March to June, 1918; no loss at all after then; flushings moderate. Local effects (June 12th, 1918): No tumour palpable on abdominal examination. On vaginal examination uterus found anteverted, bulky, freely mobile, with an ill-defined small outgrowth on left. Slight X ray dermatitis.

Last report (November, 1920): No return of periods since June, 1918. Slight flushings still occur occasionally. General health better than for years and very active.

CASE 38.—Married; aged 45; children, 1; Oct. 17th, 1914. Symptoms: Moderate and irregular menorrhagia. Local conditions: Hard nodular fibroid tumour extending to level of upper border of umbilicus. She had refused to undergo hysterectomy before consulting us.

Treatment: Total exposure 12 hr. 36 min. in eight treatments from October, 1914, to June, 1915.

General effects: Very little until after fourth treatment, then three months amenorrhœa followed by a severe period in April, 1915. Another period in May, then complete amenorrhœa. No flushings during treatments. Local effects Jan. 17th, 1916: Upper border of tumour is felt at level of pubes; on bimanual tumour reduced to less than half its size when first seen. May 19th, 1919, uterus found retroverted; approximately normal size, with several small subperitoneal nodules on surface.

Last report, November, 1920: Flushings have occurred slightly during last six months (age 51). General health very good. Leads an active life. Has lost a little weight.

CASE 39.—Married; aged 45; children, 0; miscarriage, 0; May, 1916. Symptoms: Fairly severe menorrhagia. Local conditions: Hard nodular fibroid tumour extending nearly to umbilicus.

Treatment: Total exposure, 15 hr. 50 min. in eight treatments over two years. June, 1916, to May, 1918.

General effects: After three treatments a two months' interval occurred, followed by a show for 2 to 3 days, and then complete amenorrhœa for six months. Since September, 1917, one or two moderate periods each year. Flushings slight. Local effects: In April, 1918, the fibroid had diminished to two-thirds of its original size; no further shrinkage occurred.

Last report, November, 1920: Good general health and leads an active life. One or two moderate "periods" still occur every year.

CASE 41.—Single; aged 38; July 25th, 1914. Symptoms: Menorrhagia. Diagnosis: Fibroid size of two months gravid uterus.

Treatment: Total exposure, 1 hr. 57 min. in two treatments. Last treatment Sept. 19th, 1914.

Effect on menstruation: *Menorrhagia continues and there is also* slight daily loss, Sept. 19th, 1914. Ceased to attend: Treatment incomplete.

Report, 1920: No reply.

CASE 49.—Married; aged 38; children, 1. Symptoms: Menorrhagia, headaches, debility. Diagnosis: Chronic metritis.

Treatment: Total exposure, 2 hr. 10 min. in two treatments. Last treatment, June 24th, 1918.

Effect: After two treatments period diminished to normal. General health improved. Decided to give no more treatment.

Note taken April 1st, 1920: Amenorrhœa, July, 1918, to January, 1919. January, 1919, to July, 1919, *periods every 14 to 21 days*, duration 10 days. Amenorrhœa July, 1919, to January, 1920. January, 1920, period lasting 14 days. Amenorrhœa since to April 1st, 1920. Patient refused further treatment.

CASE 56.—Married; aged 47; children, 0; May 4th, 1917. Symptoms: Menorrhagia; very marked neurasthenic symptoms. Diagnosis: Chronic metritis.

Treatment: Total exposures 3 hr. 40 min. in three treatments from May to August, 1917.

Effect on menstruation: Amenorrhœa from September, 1917, to September, 1919, when she had hæmorrhage for 2-3 weeks. Advised further treatment, but this was refused. Amenorrhœa from September, 1919, to June, 1920, when severe hæmorrhage occurred, lasting two days. Again severe hæmorrhage September, 1920. Patient has been taking thyroid extract. Advised further treatment or curettage, but this was refused. General effects: Flushings moderately severe.

Last report: Sept. 25th, 1920.

CASE 65.—Married; aged 43; children, 2; Oct. 16th, 1918. Symptoms: Very severe menorrhagia necessitating 3 to 4 days in bed. Local conditions: Bulky uterus but no fibroids, probably chronic metritis.

Treatment: Total exposure 8 hr. 40 min. *in five treatments from* October, 1918, to February, 1919.

General effects: After the first and second treatments considerable improvement, an interval of seven weeks having occurred. After third treatment a very bad hæmorrhage occurred which lasted altogether for a month. Slight flushings.

Last report, January, 1921: Menstruation still occurs at irregular intervals, but loss is moderate since treatment. Flushings only slight.

CASE 70.—Married; aged 40; children, 2; miscarriage, 0; August 6th, 1915. Symptoms: Menorrhagia 2½ years. Severe leucorrhœa. Diagnosis: Retroversion of uterus. Chronic metritis.

Treatment: Total exposuret 4 hr. 40 min. in five treatments, August to December, 1915.

Effects on menstruation: Amenorrhœa from November, 1915, to March, 1916. Regular normal menstruation ever since.

Report, 1920: Periods have been regular, 4 to 5 days, loss slight since March, 1915. General health much improved. Gained weight.

CASE 75.—Married; aged 43; children, 3; August, 1919. Symptoms: Prolonged and very severe hæmorrhages lasting from 2 to 4 weeks, with irregular intervals. Profound anæmia and debility. Local conditions: Bulky uterus, no fibroid. Chronic metritis. Patient was advised to undergo hysterectomy, but she and her husband (a doctor) both declined.

Treatment: One treatment lasting 1 hr. 50 min. was given, and this was followed by a flooding so severe that consent was given to operation. The uterus was successfully removed, and the diagnosis of chronic metritis confirmed.

January, 1921, the patient is now in very good health.

CASE 76.—Single; aged 46; Feb. 14th, 1914. Symptoms: Menorrhagia for 3 years, pain for a week before periods. Local conditions: *Hard fibroid extending to upper border of umbilicus.*

Treatment: Total exposure, 9 hr. 56 min. in six treatments.

Effects: Relief of pain. Amenorrhœa from May to November, 1914. Severe flushings. Severe losses in February, March, and April, 1915. Local effects: No change in fibroid. Hysterectomy, April 30th, 1915. No adhesions.

OPERATION FOR
REMOVAL OF THE APPENDIX IN THE QUIET PERIOD.

BY W. H. BATTLE, F.R.C.S. ENG.,
CONSULTING SURGEON TO ST. THOMAS'S HOSPITAL.

EVEN at the present day differing opinions are given in books on operative surgery regarding the merits or demerits of the various operations for removal of the appendix in the quiet period. Some of them appear to be written with an imperfect knowledge of what practical work may be required in the operation selected. An analysis of the conditions found in the abdomen after one or more attacks of appendicitis in a consecutive series of cases under the care of one surgeon may assist those who have not had large experience of *the problem. The series brought forward are the first* 1000 which came under the writer's care and were operated on by him or by a house surgeon under his supervision; the series was completed some years ago, and it is therefore possible to give some of the results at a sufficiently remote period. In THE LANCET,[1] 1910, a synopsis of 400 cases was given, and to these another 600 are now added, the two series being placed together for the purpose of this paper; in neither group is operation during an acute attack included.

At each operation the parts around were also examined, adhesions estimated and treated, and the pelvic organs examined for abnormality, displacement, or disease. In a few the kidneys, ureter, the gallbladder, and pylorus were palpated, but the operation was done because the symptoms of which the patient complained were considered to be due to a diseased appendix.

Conditions Necessary for Operation.

Any operation performed for removal of the appendix "à froid" must be without risk, should give adequate access to the part where the diseased structure is lying, permit of the manipulation required in every case, and the treatment of local complications due to inflammation, or to some separate disease. It must be possible to close the wound without any local weakness, for the patient must not be handicapped by the necessity of wearing an apparatus to reinforce a weak abdominal wall.

Causation of Fatal Results.

Under modern conditions of wound treatment any incision which opens the peritoneum is safely made, but there must be no question of even 2 per cent. of fatality. The fatal results which ensue after removal *of the appendix* in the quiet period may arise from the following causes:—

(a) *Peritonitis.*—(1) The result of accidental infection during the operation. (2) Contamination during the severance of the appendix. (3) The opening of some concealed abscess, probably of recent formation. (4) Separation of some firm adhesion giving rise to a tear in the wall of the gut, which passes unobserved. In two of the cases there was a second communication between appendix and cæcum. (5) The yielding of sutures placed in the wall of the gut or at the point of section from the cæcum, as a consequence of violent vomiting, sneezing, or coughing.

(b) *Hæmorrhage.*—Hæmorrhage into the peritoneal cavity arising from the slipping of a ligature placed on the vessels of the meso-appendix.

(c) *Other risks.*—Other risks in common with all operations, from the action of the anæsthetic either at the time or during after-treatment, and the progress of some coexisting disease, such as tubercle.

---

[1] THE LANCET, 1910, ii., 368.

The attempt to remove the appendix through a keyhole incision is not to be recommended. Anyone making this attempt is probably of the opinion quite unjustified that all cases are easy and without complications. He is not acquainted with the fact that adhesions are common and often dense, that the appendix may be attached to neighbouring organs, and is not infrequently hidden and misplaced.

State of the Appendix in 1000 Cases of Removal in the Quiet Period.

—	Male.	Female.	Ages.							Total
			10	20	30	40	50	60	Over 60	
Apparently normal	4	3	—	4	2	1	—	—	—	7
Hypertrophy	1	—	—	—	1	—	—	—	—	1
Obliterative inflammation	6	10	1	1	2	3	7	2	—	16
Catarrhal	242	269	25	153	201	72	43	16	1	511
Stricture	183	134	21	59	128	65	35	9	—	317
After abscess	71	74	14	41	45	32	8	2	3	145
Tubercle	—	2	—	1	1	—	—	—	—	2
Carcinoma	—	1	—	1	—	—	—	—	—	1
—	507	493	61	260	380	173	93	29	4	1000

This table shows the relative proportion of the various primary conditions of the appendix. *The frequency of secondary complications and their importance must be considered in more detail.*

The operation in a very stout patient may involve incision through some four inches of subcutaneous tissue and fat before the muscular wall of the abdomen is reached. The opening must be adequate and capable of rapid enlargement if the condition found demands more space for manipulation. Such enlargement must not add to the risk of subsequent hernia. There is another reason for securing plenty of space in the fat subject, and that is the necessity of closing the deep wound without catching any omentum, either with the edges of the peritoneum as they come together or by the needle as it is passed across.

It is much easier to remove an acutely inflamed appendix during *a first attack than one which has been* left to become fixed to parts around by adhesions, which are often dense and extensive. They often appear out of proportion to the severity of the attack as described by the patient. In six instances the appendix was apparently normal when removed after more than one definite attack of appendicitis. In one it was removed as a precautionary measure for a nurse who had been in charge of a fatal case of first attack.

A general hypertrophy of the appendix without any evidence of inflammatory changes is not often met with. In the solitary patient of this series, a boy, aged 16, there had been frequent attacks of abdominal pain without any rise of temperature. The attacks were not sufficient to make him stay in bed, but interfered very much with his desire to lead an active life. The appendix was 8 in. in length and very movable.

Results of Chronic Inflammation.

The results of chronic inflammation come under the main headings of Catarrhal 511, Stricture 317, and "After abscess" 145, which "pathologically" come under these two headings. We must consider these groups more closely, as together they constitute a total of 973 out of the 1000, and are therefore the most important.

1. Catarrhal, those in which one or more attacks had resulted in the formation of a fibroid deposit in the wall of the appendix, which had not produced an intrinsic stricturing of the lumen of the tube. There may be no history of an acute attack. The fibrous changes are most frequently met with as a deposit in the submucous tissue at or towards the distal end, and repeated attacks may cure by an obliteration from below upwards. Unfortunately in a large number one attack is sufficient to cause crippling of the muscular wall of the appendix, and it becomes a stiffened tube, incapable of expelling its contents. A sac for the trapping of fæcal matter is formed from which much trouble may arise from painful attacks, with or without signs of inflammation; from toxic absorption, the formation of concretions or coproliths, or from reflex action on other parts.

2. The cicatricial change may be localised (as definite and limited as that of the urethra), a stricture of the tube being formed, the results of which are ultimately dangerous. The lumen becomes obstructed; in some this leads to an acute over-distension of the parts beyond and rupture into the peritoneum. If closure is more gradual dilatation of the appendix beyond may cause a mucocele, the size of which is sometimes great. When an inflammatory attack complicates stricture it may give rise to a retention of pus and fæcal matter which escapes, although with difficulty, and produces but few local signs. If a fæcal concretion is trapped beyond the constricted part it may act like a ball valve, producing an acute distension and rupture, or produce ulceration by pressure on the mucous membrane and structures over it, which perforates into the peritoneum. The immediate danger in cases of rupture varies much according to the situation of the stricture and the amount of septic contents beyond at the time the wall gives way. Sometimes a superficial ulceration of the mucous membrane is disclosed only by microscopical examination. It is a common experience to find a stricture which has obliterated the lumen and given rise to an acute obstructive attack when no history of previous illness can be elicited. This statement applies both to adults and children. Probably some foreign body had caused a breach of the epithelial lining, and been expelled by a reflex contraction of the appendix, but the ulceration continued as a slow process, without producing any symptoms to draw attention to it until contraction had progressed to a definite obstruction.

3. Other changes of a secondary character are found in an appendix after inflammation in addition to its loss of muscular power. It may become knotted or twisted in various ways, this position being rendered permanent by adhesions.

4. The meso-appendix varies in the amount of its involvement during an attack. Its function as the conveyer of blood and lymphatic vessels renders its involvement during appendix inflammations of great moment. Thrombosis is common. Even when the appendix is apparently free from traces of past storms, the meso-appendix may be shortened in one segment, possibly causing a kink, or a more general shortening in a mesentery of a different shape may cause a corkscrew twist. It was often described as shortened, thickened, and indurated.

5. The adhesions which may form from organisation of the lymph effused during the process of limitation of an inflammatory exudation or septic invasion, vary considerably in number and extent. It is not possible to say with much certainty if an attack will be followed by adhesions which may require incision with knife or scissors, or whether the appendix will be free and of apparently normal appearance and attachments.

In 4 cases of the first series of 400 the adhesion of coil to coil *during recovery from an abscess* caused obstruction which required operation. In another (second series) obstruction followed severe intraperitoneal hæmorrhage. Not infrequently it is the strong bands fixed to surrounding parts which prove most dangerous; the wider and more dense which bind down the appendix itself, sometimes completely concealing it, tend to limit later attacks. The danger of obstruction of the bowels by bands which ensue after attacks of inflammation in the abdomen, mostly of appendical origin, must not be forgotten, nor the fact that the appendix itself may become fixed to some structure in the iliac fossa or the pelvis, to the intestine, or to the abdominal wall, and so make a snare for the small gut.

Adhesions.

The question always arises before operation, Are there any adhesions and, if so, are they likely to be numerous or dense? When the patient has a clear history of appendix abscess it is probable that there will be adhesions, and they are likely to be firm, if it is long since the attack.

In examining the cases of appendicitis comprised in this series we find that 223 out of 511 presented adhesions, which may be classified as slight (47) those which could be easily separated with the finger; moderate (75), which required some force to separate them; severe (110), which required to be divided with the knife or scissors.

The importance of previous attacks was investigated, a history of many attacks (more than four) apparently indicated that the appendix was not so likely to be very fixed.

—	Cases.	Slight.	Moderate.	Severe.	Free.
After the 1st attack	96	14	19	38	25
„ „ 2nd „	93	10	17	11	55
„ „ 3rd „	51	8	10	17	16
„ „ 4th „	271	15	29	44	183

This should be compared with the cases in which intrinsic stricture of inflammatory origin was found at operation.

—	Cases.	Slight.	Moderate.	Severe.	Free.
After the 1st attack	69	3	23	25	18
„ „ 2nd „	80	3	19	26	32
„ „ 3rd „	56	3	8	13	32
„ „ 4th „	112	3	14	18	77
	317	12	64	82	159

When dealing with a concealed appendix or with a case in which there are many adhesions, isolate the area involved with gauze wrung out in warm saline. Define the position of the intestinal tract in the adhesions, follow down the anterior band of the cæcum to the root of the appendix. Avoid force in separating any involved coil of bowel, and be careful in dividing strong adhesions. Repair lesions of the intestine, whether they are partial or complete.

Amongst the 145 cases of removal after abscess there were 87 in which the adhesions were extensive, yet at the time of removal of the appendix (usually a few days after closure of the abscess) many yielded to the pressure of the finger. It was possible by this early operation to arrange parts in their normal positions, or put them where contraction would do least harm, should the adhesions re-form. The abscess mostly occurred during the first attack.

It is quite understood that the adhesions formed as a result of the organisation of lymph effused is nature's effort to localise an inflammatory invasion; they were therefore useful to the individual so long as the attempt at invasion was continued. But as organised bands, layers, and attachments of fibrous tissue they are dangerous, interfering with normal movements of the parts, compressing and possibly snaring or obstructing the bowel. In later life these adhesions are amongst the most numerous of the causes of obstruction of an acute character. Deal therefore with these adhesions, and examine the pelvis for isolated bands; you may do much good by placing things in a normal state as far as possible.

To prevent adhesions forming as a result of operation precautions should be taken (1) to handle structures exposed in the abdominal cavity with gentleness; (2) to avoid the use of strong antiseptics, either as solutions during the operation or as applications to the skin. It is not always possible to prevent the omentum or bowel from coming into contact with the skin, and both react very readily to chemical irritants. (The use of picric acid and iodine was given up in consequence of an increase in the complaint of pain afterwards, possibly due to slight adhesions.) (3) Remember the danger of trapping omentum between the edges of the wound, or of possibly snaring it or the intestine with a deep stitch. If the wound is deep and funnel-shaped this is a real danger, especially if respiration is hurried and deep, or vomiting comes on before closure of the wound is effected. Adhesions may be very troublesome, and the patient who submits to early operation during an acute attack may avoid some years of misery.

The aseptic method is much the best in all abdominal cases. The concealed appendix may be found pointing in any direction, and even when it has been found, it may not be possible to extricate it whole from the firm bed in which it is lying. It is not infrequently the wisest plan to shell it out, leaving its adherent peritoneal sheath in the adhesions. The mucous lining is what we wish to obliterate. This method is accompanied by little bleeding. Solitary adhesions must be examined when divided to see that there is no central canal; an adherent appendix or stretched diverticulum may be divided without recognition, the result being disastrous, bowel contents escaping through the opening into the peritoneum after the wound is closed.

In the absence of adhesions the operation does not take much time, but hurried operation is never safe. An attempt to pull an adherent appendix through a keyhole opening is bad surgery. The opening must be adequate, and this can only be decided after examination. By the method employed[2] in the majority of the series given in this paper there need be no hesitation in extending the wound as far as the surgeon wishes. When the appendix is free, and the ovaries and tubes are normal, it will not be necessary to divide any nerve entering the rectus muscle. A long incision may necessitate division of nerves, but the nerve-supply above and below is adequate and no permanent weakness of the muscle ensues. It is an advantage to place the centre of the incision lower in the female than in the male; this gives better access to the pelvic organs.

If there are the remains of an old abscess or a granulation-lined cavity, possibly containing an escaped concretion, it may be cleaned with gauze and then washed out with peroxide of hydrogen. The cases in which drainage may be required are those in which an abscess of recent origin is found. It does not make any difference as regards the future strength of the abdominal wall whether the rectus sheath is incised over the middle of the muscle or more to the outer side. The principle to be remembered is the interposition of part of the uninjured muscle between the two lines of incision in the sheath.

The outer edge of the rectus is at a point three-fifths of the distance from the umbilicus to the ant. sup. spine of the ilium; therefore, if an incision is made over the mid-point between these landmarks it lies over the outer part of the rectus. If you place the cut over the middle of the rectus it is necessary to make a larger incision in the sheath to obtain room for deeper manipulations, because the outer lip of the incision is retracted with more difficulty.

Experience has shown that the appendix must be cut off level with the cæcum. No stump must be left, and the surgeon should ligature the vessels of the meso-appendix himself. There are advantages in using silk for this purpose. A satisfactory plan is the application of a clamp, which leaves a thinned peritoneal area, round which a ligature is placed. The appendix beyond is then removed between this and the forefinger and thumb, which prevent possible escape of contents. The small amount of tissue remaining is sunk in a groove, which is sutured edge to edge with No. 1 silk. The ends of this suture are tied together and the remains of the appendix firmly embedded.

In no instance was the appendix completely destroyed by disease, but in 15 there had been partial destruction. Sometimes the gap was closed by adhesions of the omentum, in others there were separated portions lying more or less in the line of the main body. Some were hard fibrous nodules throughout, others were lined by mucous membrane. Two women were admitted for symptoms similar to those which had induced them to undergo a previous operation for removal of the appendix; in both it was found that removal had been incomplete. One patient had slight evidence of fibrous changes in the thinned wall of an appendix which was distended and filled with gas, resembling a finger-stall. No cause for this unusual condition could be found. In some chronic obstructive conditions of the large gut the appendix occasionally becomes extremely dilated and as large as the big toe of an adult.

---

[2] See THE LANCET, 1919, ii., 369.

Of the cases of inflammation which were not accompanied by local stricture of the intrinsic kind, 28 showed evidence of perforation during some previous attack. In some a concretion was found outside, but there was no trace of the perforation to be seen in the wall. In 96 the appendix was kinked or fixed in a twisted position; in several this must have produced an obstruction, the presence of which added to the patient's danger, and sometimes there was a concretion trapped beyond the narrowed part. In six it was thickened and twisted like a corkscrew. In six female patients, living in different parts of the country,[3] the mucous membrane presented a curious brownish-black pigmentation in addition to other changes. The fact that the pigmentation was continued evenly to the line of separation showed that it extended into the cæcum, but there was nothing to show how far beyond this it spread. It is difficult to account for this pigmentation in the absence of any history of the administration of iron, bismuth, or mercury in the form of medicine.[4] In 97 it was much thickened, once it was the size of an adult forefinger. It is not exactly stated in how many the meso-appendix was distorted as a result of inflammation. In a few there was no naked-eye change; in the majority when the appendix showed damage the meso-appendix corresponded.

Amongst those in which definite stricture of the lumen was the outstanding change this was strictly limited to one part in the majority. Its position varied as, indeed, did its length and degree of closure. The position was recorded in most of the 317 cases. It was proximal in 99, mesial in 73, distal in 85. When there were two strictures they were disposed as proximal and mesial, 2; proximal and distal, 12; mesial and distal, 1. Multiple, the strictures being disposed irregularly, 5. There was evidence of old perforation beyond the stricture in 52, and in some, where there had been two strictures, a depressed scar was found distal to each of them. It is interesting to note that these perforations were in the line of attachment of the meso-appendix and not far from the stricture. The evidence of perforation was mostly found in those who admitted only one or two attacks. There was dilatation beyond in several, a sac having been formed of varying size, in 32 mucus was found in this dilated part, and in 28 muco-pus. In 75 the appendix was much thickened and hard, the tip being very commonly bulbous. The presence of a small amount of pus found at operation, caseation or a granulation area near, showed the severity of a previous attack. These areas were sometimes walled in and concealed by adhesions, often of extreme density.

Operation after Abscess.

Under the separate heading of "Operation after abscess," it is not proposed to say much. It is interesting to note, however, that it contains fewer cases in proportion amongst the 600 owing to the great importance attached during recent years to early operation in acute appendicitis. In the former series of 400 there were 79 operations after definite abscess, in the 600 now added there were only 66. Operation was performed in 92 instances after the first attack. The rule has been to advise operation within a short time after closure of the wounds in all cases where the appendix was not removed at the opening of the abscess. The presence of a concretion in the pus did not prevent adherence to this rule. Sixteen suffered from three or more attacks before operation was permitted. In 79 there was a stricture of the appendix. 66 showed changes secondary to a catarrhal inflammation. Of the strictures (mostly single), 29 were proximal, 30 situated in the middle third, and 18 were distal. In 57 there had been perforation; in 9 there was still a small collection of pus, probably residual, which gave no signs of its presence; in 22 there was inspissated pus; and in 2 empyema of the appendix. Where there was a weakness of the ventral scar the layers of the abdominal wall were defined and sutured during the closing of the incision, which followed the line of the old wound. Otherwise all operations were carried out through the incised rectus sheath, with displacement of the rectus inwards. In three cases the appendix was removed at a second operation because the shock which resulted from intraperitoneal rupture of an abscess was so profound when they were admitted.

Pelvic Complications.

Pelvic complications were found at operation in several females. In 25 the ovary was excised for cystic disease (3 suppurating). In one a dermoid cyst was taken away, and in another a cyst of the broad ligament. In two instances where the cystic disease affected both ovaries a paramesial incision was also made. Chronic salpingitis required removal of the tubes in two instances. Small uterine fibroids were not infrequent. Retroflexion was a fairly common complication. In two instances Meckel's diverticulum, showing evidence of previous inflammatory attacks, by adhesion to surrounding parts, &c., was removed, and the opening into ileum sutured. In the first 400 there were 5 cases of superficial thrombosis, but only 2 in the series of 600 now added. The onset of this complication during the after-treatment was usually ill-marked, and in patients who appeared to be progressing normally. In one there was thrombosis during the attack of appendicitis which preceded the operation. Gas followed by ether was the usual routine of anæsthesia in the vast majority of instances given by Dr. Z. Mennell, to whom it is owing that chest complications were few and fatalities nil.

Mortality.

In the first 400 there was one death caused by accidental infection of the peritoneum by the *Bacillus pyogenes aureus*. In the additional 600 now given there was also one death, the result of vomiting and giving way of sutures in a stout flabby woman of 56. In this case there was a partial excision of the cæcum.

Strength of abdominal wall.—In only one of the series did a complete hernia develop; this occurred in a fat agricultural labourer who had much vomiting after operation. In his case the abdominal wall was successfully repaired. In two others there was a weakness of the scar, probably due to the yielding of sutures in the posterior sheath as a result of vomiting, but no bandage (or truss) is required. If the appendix has been cleanly removed at its junction with the cæcum, and there is no other abnormal state of the abdominal organs which has been overlooked, the prognosis as to complete recovery is very good. The attacks of pain will cease and he may expect to resume work under a month. Where the precautions advised at the operation are recommended there will be no likelihood of adhesions forming later, but the prognosis in those cases where adhesions had already formed as a result of previous attacks is less certain, but often these do not produce symptoms. The cases here tabulated give some idea of the amount of illness, pain, and distress which can by saved by operation in the early hours of the first attack of appendicitis. The time lost from the working years of the individual sufferer is not easily calculated; several had become chronic invalids. The patient who has had an undoubted attack of appendicitis is acting wisely to get rid of the probable source of future trouble.

THE Galton dinner will take place on Feb. 16th at the Connaught Rooms, Great Queen-street, Kingsway, London, W.C., at 7.30 P.M. As already announced, the annual Galton address will be delivered by Mr. W. Bateson, F.R.S., at 8.45 P.M., on Common Sense in Racial Problems. The chair at the dinner will be taken by the President of the Eugenics Education Society, Major Leonard Darwin, Sc.D.

QUININE TREATMENT OF MALARIA.

BY SIR PATRICK HEHIR, K.C.I.E., C.B., C.M.G., M.D.
MAJOR-GENERAL, I.M.S. (RETIRED).

READERS of THE LANCET interested in the quinine treatment of malaria will, like myself, feel greatly indebted to Majors J. Pratt Johnson and Kenneth Gilchrist for the record[1] of their experience during the German East African campaign contained in a recent issue; the editorial note on their paper in the same issue will be welcomed as emphasising the carefully prepared, accurate and important observations of these two officers. In India we received a large number of cases of malarial infection from German East Africa, many of them both severe and heavy; in the Northern Command we found it necessary to isolate several battalions returning from German East Africa at non-malarial hill stations until their infectivity (in the presence of malaria-carrying anophelines) had undergone considerable reduction. I would ask permission to make a few remarks on their paper, and to attempt to indicate how closely their observations correspond with those of one's own experience in India before and during the war, at the same time endeavouring to lay stress upon some of the more important practical points brought out by these writers.

Large-dose Treatment.

The large-dose treatment by quinine of malarial paroxysms, both in initial attacks and in relapses and reinfections, is probably the greatest improvement of malarial therapeusis in recent times. The records of the military hospitals of the Northern Command in India show that in those malarious stations where curative quinine treatment is most persistently and intensively carried out relapses are decidedly fewer than in those where its adoption has been half-hearted. This form of treatment is partly based on the assumption that the perpetuation of the asexual cycle of malaria parasites in the blood, spleen, and bone marrow is the responsible cause of relapses. It is possible that under certain conditions the asexual forms take on a relative immunity to the toxic action of quinine, although I do not think that we have as yet sufficient evidence to justify our dogmatising on this point. So far as observations go in India we have no definite proof that relapses are caused in any other way than by latent asexual forms of malaria parasites resuming activity and multiplying in the same manner as during the initial infection. Whether under certain conditions the spores of malaria parasites become immune or partially immune to the action of quinine remains to be proved, but the assumption that they do so gives us a definite and practical line of treatment of the initial paroxysms and those of relapses. The special significance of this hypothesis rests on its application to the treatment of malaria. Small doses of quinine, even in the slighter infections, may simply render the asexual cycle relatively immune, so that larger doses, which would probably have eradicated parasites in the early stages, are later ineffectual. It seems probable that were doses larger than those usually administered during the initial infection given for the first three weeks, and smaller doses continued subsequently, there would be considerably fewer relapses. Acceptance of this view implies the necessity of getting all cases of malarial fever under quinine treatment as soon as possible.

Malarial Parthenogenesis in Man.

Ever since 1904 various authors of books on malaria have described the process of parthenogenesis of malaria parasites as occurring in man, and have depicted the stages by which it is carried out, as if it were a universally accepted and regular phase of the life-history of the parasites, and they explain that relapses are due to this phenomenon. This view, of course, had the support of Schaudinn. I personally have never seen this process, although much attention was given to the matter; nor have I met with any fellow-worker in India who has observed it. I should, however, be very reluctant to declare that it does not occur. All I am prepared to state is that the proof so far advanced is not sufficiently convincing to myself.

The ingenious suggestion that large doses of quinine arouse in the malaria parasite the instinct to seek more healthy surroundings and bring about development of the sexual stage is rather captivating, and recalls one of Sir Patrick Manson's original suggestions as to how the malaria parasite was brought into contact with the mosquito.

Disappearance of Parasites after Large Doses.

The acceptance of this view would necessitate the brushing away of some difficulties. For example, it sometimes happens that, after a few large doses of quinine, malaria parasites cease to be visible altogether. The observations made in the Malaria Depôt, Dagshai, a non-malarial hill station in India, show that in some cases malaria parasites permanently disappear from the peripheral circulation after a single intravenous injection of quinine. This sudden disappearance of malaria parasites in some cases under large doses of quinine has been a mysterious phenomenon and intrigued me for many years. At one time I was disposed to consider that quinine not only poisoned the asexual parasites, but had likewise an appreciable toxic influence on the sexual forms. This view appeared to be supported by some observations I carried out in 1909–1913, when busy endeavouring to frame measures to reduce malaria in certain cantonments in India and Burma. I will take the liberty of quoting a few out of over a hundred observations bearing on this point.

CASE 1.—On July 8th, 1909, a Garhwali, aged 22 years, anæmic, with a spleen extending to 2 in. below the left costal arch, came under observation for the first time at 10.30 A.M. Had been having paroxysms during preceding 12 days. The blood was examined and found to contain enormous numbers of benign tertian parasites. In about a quarter of an hour swarms of microgametes were flagellating; in one field (1/16 obj., No. 4 eye-piece) nine were counted, and in 25 minutes free microgametocytes were moving about on the slide. The percentage of red cells infected was 5·5, of which approximately 2·5 were gametes. There were 27 per cent. of large monuclear cells, of which 3 per cent. contained hæmozoin. One 10-grain dose of quinine in solution was given by the mouth at once and repeated at 4 P.M; a third 10-grain dose was given at 9 A.M. on the ninth, when the blood was again examined, the temperature being normal. Not a single parasite could be found in seven stained slides examined, nor in four thick-film preparations; there was still 26 per cent. of large mononuclears, but none of those seen contained pigment. The blood was examined every 12 hours for five consecutive days with negative results.

CASES 2 AND 3.—On June 26th, 1909, two Gurkha lads, aged about 17 and 18 years, were admitted into hospital both with subtertian infection. In both every field of the examined blood contained malignant tertian "rings"; the percentage of infected red cells in one was 2·8, and in the other 2·4. In the former 25 crescents were counted on an average on four slides, and in the latter 11. The younger boy was pale, and his spleen was considerably enlarged. Each got 30 gr. of quinine in solution on the 26th. On the morning of the 28th neither rings nor crescents could be found in the blood of the elder boy, and only two to a slide in the younger; five slides in each were examined. Later, microscopical examinations of the blood once a day for a fortnight were entirely negative in both.

CASE 4.—On Sept. 29th, 1906, a Gurkha, aged 25 years, returned from Assam (where he went on furlough) with an enlarged spleen, anæmia, and regular paroxysms of quartan fever. The blood contained numerous asexual quartan parasites (0·4 per cent. of the red cells were infected) and about eight spherical gametes were found on every slide. On the 29th 30 gr. of quinine in solution were given. On the 30th examination of seven stained smears of blood was quite negative, and continued to be so for 12 days, after which the man was discharged to attend daily for quinine for three months.

The disappearance of the sexual forms from the blood one now looks upon as an indirect effect of quinine only, believing that the drug kills off most of the asexual forms and thereby reduces the number that could develop into sexual forms. I am still, however, not prepared to state that quinine has no action on sexual forms. There may be explanations other than the assumption that this comparatively sudden disappearance of malaria parasites from the blood is due to the toxic influence of quinine; and I should be grateful to anyone, who reads this and has considered the point under reference, if he would give me the benefit of his observations.

Quinine and Sexual Forms of Parasites.

My own observations disagree with the statement that the sexual forms of malaria parasites do not occur in cases of malarial fever untreated by quinine. When I was a regimental medical officer we had about 100 furlough men (Gurkhas) returning at the same time every year from Nepaul with malarial infection, 25 per cent. of whom had sexual forms of parasites in their blood at the time of the first observation; none of these had received any quinine during the five months they were on leave. This is also borne out in almost every Indian village in endemic malarial districts during the malarial season. I am in complete agreement with the statement that the disappearance of crescents and other sexual forms from the blood indicates that progress is maintained in reducing the infection, and that the supply of asexual forms to provide sexual forms has been cut off. The entire disappearance of all forms, sexual and asexual, is also most satisfactory, and appears to show, as the authors of the paper under reference state, that "the infection has been hard hit and so reduced in numbers as to justify a favourable prognosis." Much of what one has stated above is more forcibly and tersely expressed in their penultimate paragraph: "It is clear that the eradication of crescents"—and, it may be added, of other sexual forms—"is satisfactorily secured by the control of the asexual generation of malaria parasites by adequate quininisation."

---

[1] A Statistical Investigation of Records of Treatment and Blood Examination in 18,731 Cases of Malaria, THE LANCET, 1921, i., 107.

Initial Infection, Reinfection, and Relapse.

I have employed the large-dose method of quininisation since 1904, and advocated it in all hospitals with which I have been connected since that time. Anterior to the date mentioned I cannot remember following any definite cut-and-dried scheme in using quinine in the curative treatment of malaria. Each case seems to have been treated on its own merits, and although in exceptional cases this has still to be done, I believe we are now in possession of data that give us a basis upon which to formulate a much more rational method of administering the drug. The scheme I worked out in 1904 is detailed elsewhere; it has been altered little since. This large-dose treatment holds good whether we are dealing with initial attacks, reinfections, or relapses. In endemic malarial places, where fresh infections are constantly liable to occur, it is practically impossible for the ordinary medical officer, who is not a malaria expert, to decide whether a particular case is one of reinfection or relapse. A careful scrutiny of each case, with close microscopical examination of the blood, and a history (if any) of the course of the infection, may give information for inferences; but such deductions lack accuracy. The usual indication of a reinfection would be a record to the effect that the preceding attack was caused by a species of parasite different from the one found in the blood during the attack under observation; this does not necessarily mean a reinfection, as a former infection may have been a mixed one, and one or more species of parasite may have died out. The point is not very material, however, as the same course of quinine treatment is indicated whether the case is a relapse, a reinfection, or an initial infection.

Curative Value of Quinine.

It is earnestly to be hoped that the remarks of Majors Johnson and Gilchrist on the limitations of curative quinine treatment in malaria will be fully considered by those who have to treat malaria and organise the control of malarial infection. It is obvious that it has a marked influence on preventive measures likewise. I am not disposed to go so far as to say that quinine is palliative only in the treatment of malaria—in a large percentage of cases it is absolutely and permanently curative, in the absence of reinfection. It does, however, fail to prevent relapses in a higher percentage of cases than was formerly thought—even when given persistently and intensively. It is this failure to eradicate the infection in some cases that has led medical officers to seek other drugs—something more efficient than quinine. In more than one military hospital I have during the last ten years, and especially during the war, felt myself obliged to interdict the use of [illegible]arsan, kharsivan, and such-like drugs, in the treatment of subtertian and relapsing simple tertian, when this was adopted to the exclusion of quinine. I daresay my action was considered arbitrary by the younger medical officers who were trying experiments on our soldiers, but I believe the prohibition was justified; anyhow, one was influenced by pragmatism and the conviction that in quinine we possess a remedy to be better trusted to render our troops efficient in a shorter time than could be effected by the other drugs named.

Practically universal experience indicates that quinine at present is the best drug as a remedy in malarial fevers. This was claimed for it by the father of British tropical medicine, Sir Patrick Manson, almost a generation ago, and that position for quinine remains unassailable to-day. As previously remarked, quinine does undoubtedly fail in a certain proportion of cases for reasons that we are at present unable to understand; this has led to its being disparaged by some medical men and to a certain extent discredited in the lay press. Personally I feel that every medical man who denounces the curative use of quinine in malaria takes upon himself a serious responsibility. I can recall the evil effect of the announcement in India that quinine precipitated attacks of blackwater fever. Without *pressing the point further, it may be reiterated that* we have overwhelming evidence proving quinine to be the drug *par excellence* in malaria, and until something better is discovered its merits should not be depreciated.

Whilst my faith in quinine as a curative of most cases of malarial infection remains unshaken, I confess that I no longer hold it to be an infallible remedy for all cases of malarial infection and all complications arising out of such infection. I have of late years often asked myself whether the search for other drugs in the treatment of malaria has been carried out with the assiduity and perseverance that it deserves. It is quite possible that in the future we may find some drug superior to quinine as a plasmocide; again, someone may discover an external application much more permanently repellent to mosquitoes than those now in use, or a plant may be revealed that mosquitoes do not like, cultivation of which will prevent their invading the precincts of our habitations, any or all of these things may occur; but until this antimalarial millennium arrives our sheet-anchor in malaria, both curatively and prophylactically, is quinine.

Tendency to Relapse in Benign Tertian.

It was interesting to note that Majors Johnson and Gilchrist observed a special tendency to relapse in benign tertian. Many who have studied the question of malaria in India for years know that benign tertian is on the whole epidemiologically a more serious form of infection in that country than malignant tertian as regards morbidity and, indirectly, as regards mortality. I referred to this point in a recent communication in THE LANCET,[2] and I need not now labour it.

Their observation that a mixed infection is more difficult to cure than a single infection will be read with much interest by many. Around this point crowd several questions calling for investigation, questions to which further reference here would be inopportune.

Syphilis and Malaria.

Their remark to the effect that the coexistence of syphilis and malaria retards the cure of malaria and the prevention of relapses by quinine, and brings about more than usual anæmia, is in accordance with one's own experience. It may be remembered by some old workers in malaria that a generation or so ago it was often stated that syphilis and malaria did not coexist. I made some remarks on this as far back as 1891, and in 1910 stated as follows: "Syphilis and malaria may not only occur in the same person, but the one disease aggravates the other, and unless the malaria is promptly treated the dual infection is a very serious matter for the patient."

Establishment of Certainty as to Malarial Infection.

In all endemic malarial places the first point to establish is that the patient is suffering from malarial infection before saturating him with quinine. Every hospital of any size should have the appliances and personnel to determine this. Many people in India who are not suffering from malaria are given huge doses of quinine over long periods. I inspected a hospital on July 6th, 1919, and saw a patient who was suffering from intermittent pyrexial attacks for 12 days. His blood had been examined and found negative as regards malaria parasites on two occasions. Blood cultures had been made and were negative to Eberth and the paras. The medical officer was greatly puzzled. The man had been suffering from toothache off and on; to this little attention had been paid. A dentist was called in and extracted a wisdom tooth; at the same time he opened a putrid alveolar abscess and brought the pyrexial phenomena to an end. This man had received 360 gr. of quinine by the mouth and four intramuscular injections of 10 gr. each of bihydrochloride of quinine. In a letter to the *British Medical Journal*[3] I mentioned the personal experience in July, 1917, of being given 45 gr. of quinine daily for three days when suffering from sandfly fever due to mistaken diagnosis.

---

[2] Researches on the Treatment of Benign Tertian Fever, THE LANCET, 1920, i., 1332.

Unsolved Problems.

There are still a great many unsolved problems connected with the treatment, ætiology, and epidemiology of malaria; some are of fundamental importance, and others, at present appearing to possess merely academic interest, may when completely elucidated be shown to have important bearings on the practical side of malaria work.

A great deal has been done since Sir Ronald Ross made his immortal discovery, and much excellent work is being carried on at the present day. One is, however, tempted to consider that something is lacking—some want of a sense of proportion as to the importance of the questions under investigation. As far as India is concerned, one hopes that the recently formed Ministry of Health will create in its Research Department special groups of expert malaria workers who will initially tabulate the unsolved problems of malaria, place them in order of precedence as regards their practical importance in the treatment and prevention of malaria, and work at them continuously until they are wiped off the slate.

The control of malaria in tropical and subtropical countries is now, as in times past, the most important economical problem of the day. As I have elsewhere stated, "this aspect of the question of malaria has been much neglected and its importance has been obscured by relatively insignificant entomological side issues."

SQUINT, MANCINISM, AND TUBERCLE.*

BY W. C. RIVERS, M.R.C.S., D.P.H.,

TUBERCULOSIS OFFICER, BARNSLEY DISTRICT, WEST RIDING, YORKS.

IN a book[1] published not long ago it was maintained that squint was about three times commoner in consumptives, and probably also in consumptives' parents, than in the non-tuberculous; that such squint seemed to favour the left eye; and that tuberculous squinters were left-handed, and gave a family history of left-handedness oftener than did non-squinters. These five points (which, so far as I know, are new) it is proposed here to examine further in a larger material.

The first comparison was as follows: Ordinary concomitant strabismus in 500 adult or adolescent consumptives, all sputum-positive, 1·2 per cent.; in a comparable control, only 0·4 per cent. Two criticisms[2] were directed to this latter figure—namely, that squint in the ordinary run of children was much commoner than 0·4 per cent. But neither my consumptive nor my control series contained any children. Moreover, a record of the incidence of squint in the young male adult population of this country, hitherto lacking, has since become available. J. D. Comrie[3] found in 10,000 military recruits (whom he stated to represent a fair sample of the community) 31 squinters—i.e., 0·3 per cent. This is remarkably close to my 0·4 per cent., because my controls comprised both sexes, and squint is allowed to affect women a little more than men—at all events girls more than boys. The proportion in controls having been thus confirmed, it seemed desirable to test also the proportion—namely, 1·2 per cent., in consumptives. Through the courtesy of Dr. J. B. McDougall and Dr. J. Rennie, and of the superintendents of various Yorkshire tuberculosis institutions, I examined a fresh series of consumptives (not all sputum-positive), finding in 352 men and 148 women 6 squinters (again 1·2 per cent.). These 6 were 4 male, 2 female, the defect being thus rather commoner in the latter sex. So that the previous comparison was exactly confirmed, whilst further corroboration resulted from renewed search of the literature. Luzzatto[4] has been struck by the frequency of lymphatic and strumous types amongst ordinary squinters. In 200 patients at a hospital clinic he found two with squint, and among squinting school children a very large majority showing the coexistence of ordinary strabismus with plain evidence of scrofulosis. As regards paralytic strabismus, 14 out of 15 children thus affected were of lymphatic-scrofulous type. All this was quite independent of any scrofulous ocular affection likely itself to cause squint.

Age.

Again, to clear up the question of age, I have examined 343 cases of juvenile phthisis in Yorkshire (191 boys, 152 girls). There were 11 squinters; 4 boys and 7 girls, yielding a percentage of 2·0 for the former, 4·6 for the latter; or combined, 3·2 per cent. To compare with ordinary school children in this country, take Bishop Harman's recent London figures[5] of 1·0 per cent. for boys, 1·8 per cent. for girls; or combined, 1·5 per cent. J. Priestley and B. Richardson (loc. cit.), for 20,000 Staffordshire school children during a recent eight-year period, give a combined percentage varying yearly from 1·1 to 1·7, girls being slightly more affected. My own control figures for South Yorkshire schools are about the same. Not stopping, then, to do more than note the apparently new fact that squint is greatly commoner in children than in adults, we reach the first conclusion that *in the subjects of some forms of tubercle squint is as much as twice or thrice as frequent as in normal persons.*

Excessive Squint in Certain Forms of Tubercle.

What forms? In my book—remembering the very few cases seen when once going round the Royal Sea Bathing Hospital, Margate—I had surmised that squint was not in excess in bone and joint tubercle. In a subsequent investigation[6] of the stigmata of predisposition to that affection, I had found in 350 children from the Alton and Sheffield hospitals for bone and joint tubercle, figures for squint actually below the normal estimates just quoted. I was collecting cases of tuberculous adenitis when I came on Luzzatto's paper. So far my results confirm his. In 50 males there were 3 squinters, and in 55 females 2 squinters—a combined percentage of 4·7, which is very high indeed when it is remembered that not quite all of these were children. Of tuberculous peritonitis I have not yet nearly enough cases to judge, but up to now, in 46 cases, 21 of them girls, no instance of squint has occurred. It seems fair, then, to conclude, secondly, that *squint is excessive in lung tubercle and in lymphatic gland tubercle, but not in bone and joint tubercle.*

As to consumptives' parents, taking unselected patients—non-squinting, of course—and their non-tuberculous fathers and mothers, I found 3 squints among 112 mothers, none among 13 fathers. Again a proportion very much higher than the normal (0·3 or 0·4 per cent.). Thirdly, then, *squint is excessive amongst the clinically non-tuberculous mothers (at any rate) of non-squinting consumptives.*

Eye Affected.

I have now particulars of 65 phthisical squinters; 48 of these squinted with the left eye. As to the normal lateral distribution of squint, the text-books appear to be silent. So I have collected 62 non-tuberculous squinters, largely from local schools. Forty of these were left-sided. The difference (73 per cent. as against 64 per cent.) seems insignificant. However, to explore the influence of age aforementioned on squint incidence, both these series have been divided into over and under 16 years old. Over 16: 42 phthisical gave a percentage of 71 left-eyed, 25 non-tuberculous a percentage of 52. Under 16: 23 phthisical gave 78 per cent., 37 non-tuberculous 72 per cent. In all the squinters, agreeably to accepted teaching, the convergent form of strabismus was much commoner than the divergent. Divergent strabismus occurred very much oftener in phthisical than in non-tuberculous girl children. However, the number of these cases is unavoidably so small that the above figures are not worth more than mention. Still, it would appear quite likely that left-eyed preference is a characteristic of squint generally, not only of squint in the tuberculous.

---

[3] Brit. Med. Jour., March 27th, 1920.

* Address to Yorkshire Tuberculosis Society, January, 1921.

Mancinism.

Left-handedness, or mancinism, occurs in 2 per cent. to 4 per cent. of the general population. I found [1] it in 2·7 per cent. of non-squinting consumptives. In 60 squinting ones it occurs 4 times (thus in 6·6 per cent.); there are, in addition, 5 cases of ambidexterity. All the left-handers are left-eyed squinters, all the ambidexters right-eyed. Of 60 non-tuberculous squinters, 6 are left-handed (10 per cent.); again, all the left-handers squint with the left eye. There are, too, 2 ambidexters, with left divergent squint. As to sex, in both series the mancinism is much more frequent amongst the males; this is in accordance with what is known of the peculiarity in question (Ogle).

The frequency of a family history of mancinism in the general population does not seem to be known. It is pretty certainly nothing like so high as in left-handers. Ogle stated that out of 57 left-handers 27 know of left-handed relatives—that is 47 per cent. Now out of the above 60 phthisical squinters, 21 know of left-handed relatives—that is 35 per cent. Out of 60 non-tuberculous squinters, 22 know of left-handed relatives—that is 36 per cent. All the left-handed squinters in the phthisical series know of left-handed relatives, and two-thirds of the non-tuberculous left-handed squinters. Right eye and left eye, the latter kind gives a slightly more frequent family history of mancinism. It is reasonable to conclude, then, fourthly, that, *whether in phthisical or in non-tuberculous subjects, left-eyed concomitant strabismus is somewhat associated with mancinism and with a family history of mancinism.*

Deductions.

These four conclusions may be shortly examined and collated. To say that tubercle causes the squint found along with it is inadmissible, because (*a*) the history was always of the squint coming first; (*b*) there were signs of phlyctenules, opacities, &c., in very few of these patients; (*c*) Luzzatto, an ophthalmologist, excluded such a possibility from his cases: (*d*) bone and joint tubercle, in which there is no excess of squint, is by no means free from tuberculous ocular complications. Indeed, the symptom of photophobia seemed to me, when working at Alton, much commoner than in tuberculous children at a dispensary, naturally from the exposure to strong light necessary in heliotherapy.

Squint and a General Tendency to Abnormality.

Nor, of course, on the other hand, can squint be a direct causal factor in tuberculosis. However, its association with that disease should not surprise us, for the insane * are highly subject to both affections. I have shown [1] that it is in just those forms of insanity in which squint is commonest that tubercle is most rife. Squint is a mark of general tendency to abnormality. Ch. Féré [7] describes it as common in neurotic families, A. Crzellitzer [8] as familially related with deaf-mutism. It is also excessive amongst albinos and in their otherwise normal relatives—an incidence which parallels the incidence in phthisis above described; that is, in excess not only in consumptives, but also, at any rate, in their mothers. This point is of distinct service in the diagnosis of phthisis. The possible left-sided incidence of squint recalls the sinistral incidence also [9] of polymastia, another abnormality which has been described as in excess in consumptives.[10] All this makes more probable the association, too, of squint with mancinism, for mancinism (C. Lombroso, Féré) has been reckoned among the stigmata of degeneracy. Savages, lunatics, and criminals show excess of mancinism (Merkel [11] and others), also sexual inverts (M. Hirschfeld). A certain relationship exists between mancinism and stammering; at least, 2 of my 62 non-tuberculous squinters stammer. Papers on this point will be within the recollection of readers. Here, then, is distinct suggestion of the development of clinical tuberculosis being favoured by an abnormal constitution, of which squint is a sign. And such suggestion becomes strengthened when we consider the above-described distribution of squint among the various forms of tuberculosis; that is, in excess in consumption and in scrofula, not in excess in bone and joint tubercle. For it would appear likely that one peculiarity of the tuberculosis of savages, and of the insane too, is excess of lung or lymphatic gland tubercle, deficiency of the osseo-articular form.

Tubercle in coloured and uncivilised communities.—The evidence as regards these communities may be thus summarised. In most accounts lung tubercle is mentioned and no other variety. British colonial reports have a classification of tuberculosis, but it is hardly ever filled in. In one for Natal,[12] however, lymphatic glandular tuberculosis is mentioned as very prevalent. In another for Basutoland [13] the totals are: phthisis pulmonalis, 117 cases; glands, 109; lupus, 43; tabes mesenterica, 7; other forms of tubercle, including bone and joint, nil. Ziemann,[14] for Siam, mentions the lungs and intestines as affected. For Samoa, Togo, Anecho, and the Cameroons, his figures add up to: phthisis pulmonalis and air-passages, 98 cases; bone and joint, 28; other organs, 2. Westenhoeffer,[15] in Chili, divides 59 deaths from tuberculosis into 45 phthisis, 9 urogenital tubercle, 3 generalised, 1 tuberculous empyema, 1 primary intestinal. Bone and joint forms are unmentioned save that one case of miliary tuberculosis had a slight tuberculous dactylitis. Another autopsy record is that of A. Borrel,[16] on Senegalese troops brought to France. In 31 cases, bone and joint lesions are only mentioned twice, and these were evidently secondary to copious tubercle elsewhere; glandular enlargement was almost uniform as the initial manifestation, and the lungs were badly affected in all. Colonel Cummins [17] enthusiastically praises Borrel's general description, and says it applies exactly to the tuberculosis of the Sudanese. Seale Harris [18] states that tuberculous disease of bone and joint is of common occurrence among Alabama negroes, although the lungs were most frequently attacked; he agrees with Osler that tuberculous peritonitis is commoner in black patients than in white. Another writer [19] opines that tuberculosis amongst Sioux Indians does not differ at all from ordinary tuberculosis. E. Metchnikoff,[20] dealing with the Russian Kalmucks round Astrakhan, gives osseous and glandular tuberculosis as commoner than phthisis; he states that these tribes are developing some immunity to the disease. Lastly, Professor Külz,[21] in a full and excellent article on the peculiarities of tuberculosis in Pacific islanders, states that while phthisis, scrofula, and miliary tuberculosis are very common, "alle die Zustände selten sein werden, die bei uns gewöhnlich erst nach längerem Krankheits-bestand aufzutreten pflegen, wie Knochen- und Gelenktuberkulose." In the above it is significant that the exceptions to the general rule just traced are nearly all in races which have been longer in contact with civilised communities, as in Russia and North America, and who therefore may be expected to be in process of immunisation—mainly racial, by selection in Darwin's and Archdall Reid's sense, but possibly slightly individual as well.

---

* To ascribe the tubercle of insane persons to bad hygiene flies in the face of the following facts. 1. Its extraordinary frequency, at least eight or ten times that amongst the sane; a disproportion twice as great as between the lower social classes and the upper ones. 2. Its scarcely lessened prevalence in new asylums. 3. The open-air life there, and the general fatness of the inmates. 4. The prevalence amongst the insane of pulmonary gangrene. 5. The comparative freedom from tubercle and gangrene of asylum [illegible]ants.

Tubercle, insanity, and mental deficiency.—As regards the insane and mentally deficient, one cannot cite public sources for the distribution in question, at least as regards this country, for even an inquiry like that of the Medico-Psychological Committee on Tuberculosis in 1901 only speaks of "active tubercle," without mentioning its location. But Dr. C. Caldecott, medical superintendent of Earlswood, an institution the age of whose patients is that common in bone and joint tubercle, is kind enough to write as follows:—

> "No doubt *pulmonary* tuberculosis is the principal form in my experience which affects the mentally defective. We really see very little of bone and joint trouble. ...... We see a good deal of glandular tubercle, and many of the little Mongolian patients seem to suffer primarily from an abdominal form of tuberculosis."

Dr. J. Shaw Bolton, of the Wakefield Asylum, writes that two forms of tuberculosis are common in the insane, lung tubercle and disseminated tubercle, both often associated with intestinal ulceration, and the latter also with enlargement of the lymphatic glands of the chest and abdomen. Affection of the ordinary lymphatic glands of the body is rare, as is bone and joint tubercle. To a third and last inquiry, addressed to another large asylum, the answer was returned that phthisis is "a long way the most common," abdominal tubercle infrequently met with, lymphatic gland tubercle uncommon, and bone and joint tubercle rare. Thus there is evident agreement in location of the tuberculosis of savages and of the insane—the disease in these two classes has other points of similarity, of course—and this location is very much that characterised by excess of squint.

However, it will not do to say that pulmonary phthisis and scrofula are sometimes predisposed to by a degenerate or atavistic want of resistance to the bacillus, shown by squint, and peculiar to these two forms of tubercle, because in bone and joint disease one finds in excess other degenerate or atavistic stigmata. I found[6] ichthyosis, persistent lanugo, and red hair to be so. Bowen[22] and Renshaw[23] have separately advanced an atavistic theory of origin of ichthyosis—a view further confirmed by the existence in Europe of a tribe in which it is the normal condition. I gave Darwin and Lord Avebury as authorities for the atavism of red hair, and, indeed, Eusebius, Broca, Topinard, and recently Kohlbrügge,[24] might have been added; while several writers have noted the affinities of red hair with albinism—indeed, the affinities are like those of squint, for red hair is not only common in albinos (cf., the rufous albino), but also in normal relatives.

Perhaps, then, squint in tuberculosis may be the sign of some abnormality predisposing to phthisis and scrofula, not to osseo-articular lesions; thus an abnormality in connexion with the respiratory tract, say; most likely of its lymphatics, the lymphatic system, according to Virchow, being the one most subject to variation. While, conversely, red hair (not excessive in phthisis, according to F. C. Shrubsall[25]) may be the sign of another abnormality specially predisposing to bone and joint tubercle, possibly undue skin permeability. Ichthyosis, by the way, is in excess both in phthisis and in bone disease. However, there are difficulties in the way of this hypothesis. One is the view that osseo-articular tubercle is secondary to tubercle of the bronchial glands. Another, that red hair is in excess in scrofula as well as in bone and joint disease.

Conclusion.

These are dark matters. Probably both factors act, with others as well. There is a general constitutional susceptibility; there is also some special vulnerability-producing anomaly. I have not enough cases of tuberculous squinters to judge whether or no nasal defect is associated. But be the exact pathogenesis as it may, there can be small doubt of the existence, in more than one form of tubercle, of unmistakable stigmata of predisposition; unmistakable, but, like other signs of that sort, strangely neglected and ignored. Take only the significant phenomenon of squint being much commoner in ordinary school children than in ordinary adults. It might have been predicted; we know from school medical officers that very few working-class children get cured of squint, but we also know that an undue proportion of these squinters are destined to find the asylum and the prison. What use does preventive medicine make of that knowledge? Now add that an undue proportion will also become tuberculous or the mothers of the tuberculous, and that into the bargain there is probably a considerably higher general mortality amongst them than amongst their school fellows. The neglect becomes serious. Of such neglect one great cause is the current undue regard for pathology and bacteriology, in spite of their many failures and false claims in tuberculosis; and the juvenile conception that obtains of research as something necessarily involving the apparatus of the physical laboratory—unfortunate reversal of precedence between temperament and technique!

THE INCIDENCE OF CONGENITAL SYPHILIS AMONG THE NEWLY BORN.[1]

BY S. M. ROSS, M.D. EDIN., D.P.H.,
BACTERIOLOGIST TO THE DERBYSHIRE COUNTY COUNCIL;
AND
A. F. WRIGHT, M.D. EDIN.,
LATE BACTERIOLOGIST TO THE STAFFORDSHIRE COUNTY COUNCIL.

THE object of this investigation was to determine if possible the incidence of congenital syphilis among the newly born in a mining town and an industrial town in one of the Midland counties. The cases were entirely unselected, and in no instance had either parent been treated for recognised syphilis. It must be generally admitted that our knowledge of the transmission of syphilis is very incomplete, and that the term "congenital syphilis" is very loosely applied. Cases are dubbed congenital syphilis on the flimsiest of data, while others are missed through want of proper appreciation of symptoms slight in themselves, but the only visible manifestations of this insidious disease, where a Wassermann reaction might have enlightened the practitioner as to the true state of affairs.

John A. Kolmer, of Philadelphia, who has published much original work on syphilis, holds that—

> "Every untreated or inadequately treated syphilitic of either sex, and particularly the woman of child-bearing age, is potentially capable of transmitting the disease, and that the number of such persons must be appallingly large," and secondly, that "it would appear quite certain that the fœtus possesses no natural resistance to infection with *Treponema pallidum* in so far as its own tissues are concerned, and that it may be infected through the mother at any time from conception to late in pregnancy."

---

[1] Report to the Medical Research Council on the Wassermann reaction of placental blood in a series of 340 unselected cases in a Midland county.

Any figures based upon the examination of placental blood alone will give a probable under-estimation of the amount of congenital or prenatal syphilis in the general population. Dr. P. Fildes, in a report to the Local Government Board on the prevalence of congenital syphilis among the newly born in the East End of London, 1915, states that "only a minority of syphilitic women induced this positive reaction in the umbilical cord serum," and this view is held by Dr. Amand Routh (Charing Cross Hospital), Dr. Morna Rawlins (Guy's Hospital), and A. F. W.

Collection of Material.

For the collection of the material employed in this investigation, for the mining area two midwives with a large working-class practice were chosen, whose technique in midwifery and trustworthiness in carrying out instructions could be relied on. They were instructed that the cases were in no way to be selected, and that with each case a few essential particulars were to be sent.

The particulars demanded were as follows: name, age, address; date of marriage, number of pregnancies, abortions or miscarriages and period; patient's health, husband's occupation, and husband's health.

The blood was taken from the placental end of the umbilical cord immediately after it was severed from the infant. Sterilised collecting tubes were supplied from the county laboratory, and it was impressed upon the midwives that strict aseptic precautions should be taken in the collection of the specimens. These specimens were then posted to the county laboratory, and after removal of sufficient serum for S. M. R. were forwarded to the Central Hospital, Lichfield, for A. F. W. The period of time covered by the investigation was 16 months (1918–19).

Procedure of Investigation.

The procedure of the investigation into the specimens was decided at a preliminary meeting of the two investigators, after which there was no comparison of notes and no discussion about the results until the investigation was completed. It was decided that each investigator should employ a different method of test; those having been chosen, the same standard was to be used throughout the investigation, and the tests were to be batched along with the ordinary routine Wassermann testing at each laboratory to ensure absolute impartiality. Thus S. M. R. employed Professor H. R. Dean's technique, in which the complement factor is constant with variations in serum, whereas A. F. W. used Colonel L. W. Harrison's method, in which the serum factor is constant and the dose of complement varies. It is thus obvious that as wide a field as possible of technique and experience was brought to bear upon each individual specimen.

It is regretted that it was impossible to get later specimens from either mother or child; it will be readily realised that it was inadvisable in many of the cases to acquaint the parents with what was being done, owing to the risk of misunderstanding and family recriminations. In a considerable number of instances S. M. R. visited the mother to make tactful inquiries into her obstetric history, but owing to the absence of any cursory physical signs of syphilis in parent or child she was either refused or deemed it inadvisable to press for a further blood examination.

Mining Area: Summary of Results.

The result of the investigation into the 300 cases collected in the mining area may be summarised as shown in the table.

In 284 cases, or 94·6 per cent., the results of both workers were identical, 10 cases, or 3·5 per cent., being definitely positive.

1. In 5 cases A. F. W. found a trace of complement deviation which was not found by S. M. R. As this was insufficient reaction to be reported as even a partially positive result, he is of opinion that it was probably due to delay in transit, causing increased deviability of the serum. 2. In 5 cases there was marked disagreement, S. M. R. reporting two specimens positive which A. F. W. reported negative, while 3 S. M. R. reported negative which A. F. W. reported positive. Whether this class of five is due to mistakes in technique or variations of the same on the part of one or the other is so open to debate that it is beside the point to discuss here.

Table of Cases Found Positive by both Observers.

No.	Age	Month and year of marriage.	No. of preg.	Patient's health.	Husband's occupation and health.†	S. M. R. result.	A. F. W. result.
P5	30	May, '04. Dec., '17.	4	Not good. Very anæmic.	Collier.	1–80 +++++	++
P25	32	May, '04.	6*	Has had bronchitis and asthma, rheu. fever, infl. lungs.	Labourer	1–10 ++	++
P77	—	Oct., '01.	8	Had anæmia.	Police.	1–10 ++	±±–
P150	32	Dec., '10. Dec., '17.	4	Good.	Collier.	1–40 ++++	±±–
P152	19	Mar., '18.	—	Had gastric stomach.	"	–20 +++	++
P178	28	Aug., '08.	4	Good.	Missing soldier.‡	1–20 +++	++
P251	35	June, '14.	2	"	Dis. soldier.	1–10 ++	++
P258	23	Mar., '19.	—	"	Collier.	1–5 +	+–
P273	28	Dec., '11.	2	"	"	1–5 +	+–
P285	33	Unmarried.	5	"	—	1–20 +++	++
D39	—	1918.	1	"	Machine ruler.	1–80 ++++	++

* 1 Abortion, 6 weeks. † In each case the husband's health was good.
‡ Patient had a child by another man.

Two specimens cannot be reported on by both workers owing to the control tube not being completely hæmolysed. A. F. W. reported one such failure in a case reported positive by S. M. R., while S. M. R. reported one control tube not hæmolysed in another case which A. F. W. reported negative.

One specimen could not be reported on by either worker.

Industrial Area: Summary of Results.

A similar investigation was also carried out amongst the patients of a large charity practising midwifery in an industrial town in the Midlands, but owing to circumstances over which the investigators had no control only 40 specimens were sent. In this series one case was found positive by both observers, a percentage of 2½. Unfortunately, owing to the difference in the numbers of specimens from the two towns no sort of comparison into the infection of the two areas can be deduced. At the same time it was deemed more illustrative to keep the records apart, as the incidence of 1–40 in the latter town would unjustifiably reduce the positive percentage given in the former series.

Conclusion.

It must be realised that the number of specimens dealt with is too small to draw any definite conclusions from, but the percentage of positive reactions obtained is significant and calls for further investigation in wider areas: first, among unselected cases, and secondly, from those where either parent is known to be infected, so that the reliability of the test may be definitely gauged from the results achieved. The latter investigation could easily be arranged in the lying-in homes of infected patients. When one takes into consideration that women in the latter stage of pregnancy tend to give a much less positive Wassermann reaction than the history of the case warrants, and that congenitally syphilitic babies tend to give a negative Wassermann reaction until a month or so after birth, whether the complement-deviating substance in the placental blood is indicative of syphilis in the mother and not according to Fildes in the child, or in the child and the mother according to Kolmer,[2] the facts are that 3·5 per cent. specimens of placental blood were found positive by two observers using entirely different methods in different laboratories, and we presume to repeat that these results are highly suggestive of the prevalence of apparently undiagnosed syphilis in the general population.

---

[2] Archives of Pediatrics, 1920.

In conclusion, both workers would like to express their great indebtedness to their laboratory assistants, C. F. Peckham and Corporal R. W. Jones, Central Hospital, Lichfield. The incidental expenses of the research were defrayed by a grant from the Medical Research Council.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

◆

A CASE OF MYOCLONIC ENCEPHALITIS.

BY SIR JAMES PURVES STEWART, K.C.M.G., C.B.,
SENIOR PHYSICIAN TO THE WESTMINSTER HOSPITAL;
AND
E. SPENCER SCOTT, M.D., B.CH. CANTAB.

THIS dramatic and fatal type of encephalitis is so uncommon that the following case seems worthy of being placed on record.

The patient was a man of 58, free from neuropathic family taint, with an excellent personal history, active, athletic, and of temperate habits. Jan. 17th: Patient complained of sharp pain in the left shin-bone, just below the tuberosity of the tibia. There was exquisite tenderness on slight touches over this spot, but no redness or swelling. Temp. and pulse normal; no history of any local injury. During the day the pain became so intense that bone disease was suspected. Local applications of iodine and later antiphlogistine were used and aspirin was given internally. Jan. 18th: The pain and hyperæsthesia had shifted to the outer side of the left knee and extended down the leg to the outer side of the foot. The old tender spot on the tibia had gone. The patient was now restless and excited and developed sudden jerking movements of the abdominal muscles and the proximal muscles of the arms and thighs. Jan. 19th: Pain in the leg disappeared and did not recur. He was mentally confused and showed a mild delirium of toxic type. He was occasionally disoriented, and had the idea that he was in the country visiting a friend, who had, in fact, been dead for a year. Temp. and pulse remained normal. Jan. 20th: Patient was more excitable, and his delusions were more vivid; he was excited and voluble. There were well-marked spontaneous sudden myoclonic jerks, chiefly of the abdominal muscles, but also affecting the lumbar, lower pectoral muscles, and at times the muscles of the upper arms and thighs. These occurred irregularly at the rate of 14–15 per minute, and produced sudden grunting respiratory movements. The optic discs, pupils, and cranial nerves were normal. There was no motor weakness of the limbs or trunk, but voluntary movements were abnormally rapid and jerky. The knee-jerks and ankle-jerks were normal and the plantar reflexes flexor. The abdominal reflexes were absent. Kernig's sign was negative and there was no cervical rigidity. The temperature was normal, but the pulse was beginning to rise and reached 112. Heart, lungs and abdomen, and urine were normal. It was attempted to induce a fixation abscess by means of 20 minims of oil of turpentine injected into one deltoid muscle. Urotropine, 10 gr., was administered by the mouth six-hourly. The temperature rose the same evening to 100°.

Jan. 21st: Patient was distinctly worse. T. 99°–102°; P. 120. He slept badly in spite of medinal, chloral, and bromide. The myoclonic jerks were more severe, and the delirium more intense. Incontinence of urine was now present. Jan. 22nd: T. touched 103° during the night, but after a hot pack it fell gradually to 99·8°. Patient still mentally confused and completely disoriented, but replied to questions and had no paralysis. The sudden myoclonic jerks were more marked than ever, occurring irregularly, chiefly in the abdominal muscles. Knee-jerks normal. On examination of cerebro-spinal fluid no excess of pressure was found. It contained 5·38 lymphocytes per c.mm. and was free from organisms. 10 c.cm. of the fluid was reinjected into the spinal muscles at the time of lumbar puncture in the hope of furnishing an autogenous vaccine. Later in the evening the patient became lethargic and the knee-jerks could no longer be elicited. Jan. 23rd: The temperature ranged between 104·6° and 101·8°. The pulse steadily rose to 160 and the respirations to 45–50. The myoclonic jerks diminished in intensity and disappeared. Jan. 24th: T. 104°, P. 160, R. 50. Later the pulse became uncountable, and the patient died with a temperature of 103°. No autopsy was obtained.

Remarks.

The foregoing case corresponds in all essential features with those already described in 1920 by Sicard and Kudelsky[1] in Paris and by Ellis[2] in London. Its diagnostic phenomena are the intense initial root-pains, succeeded after a few days by acute myoclonus and delirium of toxic type, culminating in lethargy, coma, and death. The course of the disease in this case, from start to finish, was only seven days.

A NOTE ON THE RELATIVE ACTIVITY OF THE

FAT-SOLUBLE ACCESSORY FACTOR

IN COD-LIVER OIL AND BUTTER.

BY S. S. ZILVA, D.SC. LOND., PH.D. GIESSEN, F.I.C.,
AND
MASATARO MIURA, M.D. TOKYO.
(From the Biochemical Department, Lister Institute.)

THE therapeutic value of cod-liver oil, especially in the treatment of rickets, has long been appreciated by the clinician. The cause of this remarkable potency has not yet been satisfactorily explained, but the results of recent researches on the accessory food factors strongly favour the view that it is due to the presence of the fat-soluble factor in the oil. Professor Edward Mellanby's experiments with puppies point to the great probability that a deficiency of this factor in the diet is associated with the ætiology of rickets. Cod-liver oil, however, has shown itself always in the treatment of rickets to be superior to other substances which contain the fat-soluble factor. Results obtained by us in connexion with another inquiry seem to offer a possible explanation to this apparent inconsistency.

Our present knowledge of the distribution of the fat-soluble factor in nature is of a qualitative character. It is based on a technique which consists of feeding young rats on a diet adequate in every other respect, but lacking the factor. On such diet the animals decline, but on the addition of a substance containing the principle they resume normal growth. We have been engaged for some time in an investigation with the object of working out a method for the estimation of the fat-soluble factor on quantitative lines. From numerous experiments we have succeeded in ascertaining the necessary conditions under which results of a quantitative nature could be attained, and the method so far worked out, although not perfect, affords the opportunity of comparing the relative content of the fat-soluble factor in various substances with a reasonable degree of accuracy. In this investigation we had the opportunity of testing a variety of substances, and we were struck by the extremely high potency of cod-liver oil. This was specially marked in the case of a sample of crude unrefined cod-liver oil, which was found to be 250 times as potent as butter. The samples of refined cod-liver oil which we examined, although not so active as the crude oil, were also far superior in their activity to butter. It is our opinion that this superiority in potency of cod-liver oil to other substances is responsible for the remarkable results achieved with it therapeutically. Unfortunately, in order to satisfy the requirements of the public there is a great tendency to produce brands of cod-liver oil which retain little of the characteristic taste and which appear almost colourless. In order to achieve this, very drastic means may often be employed which conduce to the partial or even total destruction of the accessory factor. In this connexion one may point out the great instability of the fat-soluble factor when exposed to air (Hopkins, 1920, Drummond and Coward, 1920) and ozone (Zilva, 1920), the latter substance being very often employed as a bleaching agent in many industries. It is hardly necessary to point out the serious consequences which might arise if in the process of refining this exceptional activity of the cod-liver oil were to be vitiated or destroyed in the manipulation of certain preparations.

The expenses of this research were defrayed from a grant made by the Medical Research Council, to whom our thanks are due.

ROYAL SOCIETY OF MEDICINE.

SECTION OF SURGERY.

Repair of Fractured Mandible.

A MEETING of this section of the Royal Society of Medicine was held on Feb. 2nd, Mr. W. G. SPENCER, the President, being in the chair, when Mr. GILBERT CHUBB showed cases and radiograms illustrating the technique employed and the results obtained in the Repair of Fractured Mandible by means of the Free Autogenous Bone Graft. An account of his demonstration will appear in a subsequent number of THE LANCET.

Mr. G. E. EDINGTON read a paper on

Meckel's Diverticulum as a Cause of Intestinal Obstruction.

This vestige of a primitive condition was found, he said, by the practical surgeon to assume some prominence in various conditions, of which the principal were umbilical fistula, intestinal obstruction, and diverticulitis. He contributed notes of four cases which illustrated the part which the diverticulum might play in the ætiology of intestinal obstruction.

The first case was that of a youth aged 17; *the diverticulum was adherent to the umbilicus and ensnared a loop of ileum.* There had been previous attacks, and death occurred within 48 hours of the operation from paralytic ileus. Two days before the patient was first seen he had been seized with umbilical pain; the bowels moved about the same time, with which occurred vomiting. Repeated enemata failed to procure further evacuation. The three previous attacks had responded favourably to enemata. Examination showed no very great tenderness; there was dullness over the lower abdomen and in both flanks. At the operation the diverticulum was seen to arise from the side of the ileum to the left of the antimesenteric border, about 16 inches above the ileo-cæcal junction, and as a thick and rounded cord it passed downwards and inwards across the ileum. Externally the cord was continuous with the gut, and internally it passed inwards behind some distended coils and then upwards in the middle line to the umbilicus, to which it was adherent. The vertical portion was found to be much distended. Its blood-supply was obtained from the mesenteric vessels, and was in a fold which sprang from the under surface of the ileum, close to the mesenteric attachment, and ran along the mesentery to the upper (jejunal) side of the diverticulum. Vomiting came on the day after the operation and later became fæculent, and the patient died on the second day.

The second case was that of a boy, aged 10 years, in whom the *invaginated diverticulum formed the commencement of an ileo-ileal and later an ileo-colic intussusception.* Eight days previously there had been vomiting and severe abdominal pain, from which the patient recovered in a few hours. Five days later there was a recurrence of vomiting and pain, and a dark motion (? melæna) was passed on the following day. On admission to hospital the abdomen was rigid but not distended, and tenderness was especially marked about the umbilicus. Under an anæsthetic a hard mass was palpable behind the right rectus abdominis muscle about the level of the appendix. At the operation the ileum was found to be narrowed and fixed downwards and backwards towards the pelvic brim, where the bowel passed into an intussusception. Beyond this point the lower ileum was bulky, and the movable contents could be felt to extend for a distance of about 6 inches into the ascending colon. The intussusception was resected. From the apex of the intussusception hung a pyriform structure 5·5 cm. long by 3 mm. at its origin and 11 mm. at its thickest part. This was cut open and found to be an invaginated Meckel's diverticulum. Death from shock occurred early on the following morning.

The third case was that of a boy, aged 7 years, in whom a *loop of bowel was constricted by the diverticulum having adhesions to the mesentery.* Operation was followed by recovery. Two days before the patient was first seen vomiting and severe abdominal pain had set in and the bowels were moved at intervals. The vomiting continued irregularly, but there was no motion of the bowels after the following day. On this day he seemed well during the forenoon and in the evening castor oil was administered. At 1 A.M. he again vomited; he was collapsed, there was no radial pulse, the pupils were dilated, he was very restless and pointed to the left side of the abdomen as being painful, and coils of intestine could be seen. At operation a loop of the small intestine was exposed, which was very dark in colour and constricted by a Meckel's diverticulum, with adhesions to the mesentery. The diverticulum was excised, as in appendicectomy, and recovery was uneventful.

The fourth case was that of a woman, aged 37 years, in whom the Meckel's diverticulum was *adherent to the umbilicus and, along with the ileum, encircled and obstructed an abnormally free ascending colon.* In this case, also, recovery followed operation. When first seen the patient had acute pain in the lower abdomen of about 20 hours' duration, followed by continuous vomiting of whatever she swallowed. Two days previously there had been a good motion, but the bowels had not acted since. There was no history of previous abdominal troubles, but she had just recovered from pleurisy. Palpation was greatly hindered by very marked tenderness over McBurney's point and the infra-umbilical region. The pulse was 68 and intermittent; the temperature was normal; the tongue was clean and the abdomen was flaccid and suggested an early stage of acute obstruction rather than appendicitis. Under an anæsthetic there seemed to be a bulky swelling behind the lower half of the right rectus. At operation the cæcum was seen to be greatly distended and the appendix was normal. The swelling behind the rectus was caused by a Meckel's diverticulum, forming a firm, bluish, sausage-like structure extending up to the umbilicus, to which it was adherent. At its lower end the diverticulum passed downwards and outwards over the front of the colon, was narrowed and showed an axial twist. A double course of small intestine was found tightly encircling the colon above the level of the diverticulum. The diverticulum was found to arise about 12 inches above the ileo-cæcal junction close to the mesenteric attachment, and there were many old peritonitic adhesions and resulting fossæ in the neighbouring mesentery. The cæcum and the lower half of the ascending colon had a complete investment of peritoneum, rendering them abnormally mobile.

In discussing the cases Mr. Edington dealt first with (1) the anatomical details of the diverticulum, and (2) the details of the obstruction.

With regard to the former, he drew attention to the fact that in two of the cases (1 and 4) the extremity of the diverticulum was definitely attached to the umbilical scar. In one case (2) the diverticulum was quite unattached and had become invaginated into the ileum and formed the starting-point of an intussusception. In the remaining case (3) a band stretched from the apex of the diverticulum to the mesentery and formed the constricting agent, and in this case there were, further, membranous adhesions. Halstead reported 69 cases of obstruction of the bowel, in 63 of which attachment of the diverticulum was noted. Of the 63, 48 (76·19 per cent.) had an attachment, and 15 (23·8 per cent.) were free. Thus an unattached diverticulum was responsible for the obstruction in less than a quarter of the cases. Analysis of the 48 cases in which attachment was present showed that details of the attachment were given in 45. The various points of attachment were: to mesentery (23), umbilicus (15), small intestine (3), omentum (1), transverse mesocolon (1), and periappendicular exudate (1). Attachment of the tip of the diverticulum to the mesentery or to the umbilicus was by the remains of the omphalo-mesenteric vessels; attachment to other points was probably by inflammatory adhesions, and this, according to Halstead, rarely occurred. Cahier, on the other hand, stated that the diverticulum normally lies free in the abdominal cavity, and that adhesions, when present, are often of inflammatory and not congenital origin. According to him adhesions may follow diverticulitis, the lesions of which are analogous to those of appendicitis.

With regard to the details of the obstruction, each of the cases of attached diverticulum presented different details.

In Case 3 the terminal cord or thread adhered to the mesentery and produced a band under which a loop of bowel was snared. In Case 1 the contracted proximal portion of the diverticulum seemed to act as a band under which a loop of bowel had passed; but, in addition, several loops had passed forwards and lay between the diverticulum and the anterior abdominal wall. It was difficult to explain the mechanics of the obstruction in this case. Possibly in the first stage the passage forwards of the ileum over the diverticulum made the proximal part of the latter taut and so allowed of the constriction of a loop lower down near the origin of the diverticulum. If this were the sequence of events it would be fair to consider the obstruction as being due partly to volvulus and partly to band. In Case 4 there was an abnormally mobile colon and cæcum which had travelled inwards behind the diverticulum and then passed down in front of its proximal part. Repetition of this manœuvre led to the relationship of parts found at the time of the operation. There was no torsion of the colon, but the narrow proximal part of the diverticulum showed a very distinct twist. This case, he thought, must be looked upon as one of volvulus, the portion of the gut moving with the clock. In Case 2 the primary cause of the obstruction was invagination of a free diverticulum. In the cases collected by Halstead this form of obstruction occurred in seven of the 15 in which the diverticulum had no attachment.

Speaking of the symptomatology, Mr. Edington said that cases in which obstruction was caused by a Meckel's diverticulum presented little to distinguish them from acute obstruction generally.

According to Halstead, in the great majority of cases the onset was sudden and the symptoms were characteristic of acute obstruction. Porter stated that except where the umbilicus was patulous a positive diagnosis without laparotomy was usually impossible. The following signs and circumstances had been mentioned as pointing to obstruction by a diverticulum:—(*a*) Age: Halstead's statement that it usually occurred in childhood or in young adults was supported by the cases just reported. (*b*) Sex: Porter gave the proportion of males to females as greater than 3 to 1, a proportion which, he thought, supported the view that trauma was to some extent an exciting cause. (*c*) Previous attacks: Such, in minor degree, had been noted in the histories. Only one of the present cases (1) gave a history of such, but possibly there was a previous attack in Case 2. (*d*) The seat of tenderness was usually on the right side at the level of, or just below, the umbilicus, and was likely to lead to confusion with appendicitis. Halstead mentioned that where the diverticulum was attached to the umbilicus Berard laid great stress on the exquisite sensitiveness of the umbilical region. This was marked in Case 4 and contrasted with the usual signs of appendicitis; but it was also noted in Case 2, where the diverticulum had no attachment to the umbilicus. (*e*) Other malformations might, if present, give a hint as to the cause of obstruction, but their absence meant practically nothing. In Halstead's paper a review of 69 cases showed nothing beyond the presence of hare-lip in one only. In the present series of cases no external malformations were noted, with the doubtful exception of a puckered condition of the umbilical scar in Case 4.

With regard to *treatment*, these cases, showing signs of acute obstruction and simulating acute appendicitis, called for immediate operation. The obstruction being relieved, the diverticulum should be excised, and in excising care must be taken not to "borrow" too freely from the wall of the bowel and so cause a narrowing of its lumen. This precaution must be all the more observed because of the narrowing of the bowel which already existed at the seat of origin of the diverticulum.

The paper was discussed by Mr. HOWELL EVANS and Mr. GARNETT WRIGHT.

SECTION OF OBSTETRICS AND GYNÆCOLOGY.

A MEETING of this section of the Royal Society of Medicine was held on Feb. 4th, Professor HENRY BRIGGS, the President, being in the chair.

Yearly Tenure of the Office of President.

Mr. COMYNS BERKELEY spoke in support of a resolution, already passed by the Council, that the President should hold office for one year only. Mr. Berkeley explained that the resolution was not retrospective, and thus would not affect the tenure of office of the present President, but he supported it in order that some of the young men who were doing so much work for the section would have a reasonable chance of attaining to the honour. The resolution was passed unanimously.

In the absence of Mr. F. C. PYBUS, his paper on

An Unusual Type of Tuberculous Peritubal Cyst

was read by the senior secretary.

The patient, aged 20, in October, 1918, had had a laparotomy for (?) tuberculous peritonitis with ascites. Some ascitic fluid had been removed and the abdomen had apparently been washed out with saline and closed. Ascites recurred, with constipation. Mr. Pybus first saw the patient on the operating table, when he was asked to perform a second laparotomy. He evacuated a large amount of fluid, at first straw-coloured, and then turbid, with flakes of lymph. The viscera could not be found, and the hand entered a large cyst with a smooth wall, extending from the upper abdomen to the depths of the pelvis, where two papillomatous masses were found and eventually identified as the enlarged fimbriated ends of the Fallopian tubes. The cyst wall was separated and the ampullary end of each tube was amputated. The ovaries were conserved. The intestines were much compressed into the upper and posterior part of the abdomen, and no gross tuberculous lesion could be detected. The patient (December, 1920) is in good health. On examination sections of the cyst wall and of the papillary masses showed that each was tuberculous.

Mr. Pybus had found it difficult to determine whether the cyst was the result of a primary tuberculous peritonitis with encapsulation, involving the tubes, or of a primary tuberculosis of the Fallopian tubes, with pelvic encapsulation and gradual expansion into the abdominal cavity; a point in favour of the latter view was that the ovaries, though attached to the cyst wall, escaped involvement in its cavity.

Dr. T. WATTS EDEN read a paper by himself and Mr. LIONEL PROVIS on the

X Ray Treatment of Uterine Fibroids and Chronic Metritis,

based upon a record of 76 cases, which appears in full in the front part of the present issue of THE LANCET.

The PRESIDENT thanked the authors for a valuable paper, and said he had received messages from Dr. R. Knox and Dr. Ironside Bruce regretting their inability to be present.

Dr. N. S. FINZI also thanked the authors. He said that the principle of X ray therapy was that the same dose has a different effect on ovaries and on fibroids from that which it has on the surrounding tissue. The difficulties, however, of treating a structure 3 to 4 inches from the surface was that the same dose could not be given to the skin and the ovaries from the same port of entry, as the rays fall inversely as the square of the distance from their source, and because the intervening tissues absorb a proportion of the rays. There were two methods of meeting this difficulty: one was the Freiburg method, which consisted in the use of a large number of ports of entry, with the tube close to the skin. The rays were directed towards the ovary on each side, and the radiation was supposed to overlap thereon. The other method, which Dr. Finzi preferred, removed the tubes farther from the skin, thus diminishing the difference between the dose given to the ovaries and that given to the skin. The total exposure-time by the second method could be brought down to 15 min. per series of treatments, whereas the Freiburg method took three to four hours. He used only three ports of entry in thin and four in stout patients. He understood that the Freiburg technique had been given up by its originators in favour of this latter method. Dr. Finzi disagreed with Dr. Eden as to the timing of the treatment; he preferred the week preceding the period, when the parts were more vascular and sensitive. There were not an undue proportion of cases in his experience in whom the first period after treatment was excessive. As to dosage, it was impossible accurately to measure the amount given to the ovaries. In Germany they had tried to estimate it by substituting for human tissues an equivalent thickness of water; but this did not work out right through bony structures, nor was it quite accurate, though approximately so, even through skin and muscle. As to the relative value of radium and X rays, as a rule Dr. Finzi used the latter, but in some cases radium was more useful and it could be used for all. The action of radium was more rapid; it was rare to get an excessive first period after its use, and it was thus especially useful in cases complicated by severe anæmia where X rays were contra-indicated, and where operation, even accompanied by transfusion, was not free from danger. As to number of applications, radium often need only be used once, and seldom more than twice. The action of radium was more localised and tissues round the uterus received but little radiation. As to the disadvantages of X ray treatment, pigmentation and depilation did not matter much, but some late and serious after-results—caused by infection of damaged skin—had been reported from abroad. However, these were unlikely except after the prolonged treatment necessary for carcinoma. The internal after-results in certain patients who were operated on after X ray treatment were found to be the formation of an abnormal number of adhesions and of a hard and dense substance resembling cartilage round the ovaries; X ray treatment thus in many, though not in all, cases increased the difficulty of subsequent operation. Among contra-indications were the age of the patient; sometimes untoward results occurred in the very young, and the nearer the menopause the better the result. As a rule, cases under 38 were excluded; Dr. Finzi's cases were usually over 40. A degenerating fibroid or an inflammatory condition in structures round the ovary were also contra-indications. A dormant pyosalpinx might be lighted up; possibly this is what had taken place in the case described by Dr. Eden. Dr. Finzi had used the treatment in malignant cases, with much bigger doses and longer exposures. As to size, he had treated fibroids coming up to the ensiform cartilage, and had got considerable diminution, progressive for months and years. After the first six months the growth was just above the umbilicus, and at the end of the second six months below the umbilicus. Cases of post-menopausal treatment had been reported from abroad, in which fibroids had shrunk in size. This showed that there was a direct action on fibroids as well as action on the ovaries. Pregnancy was a contra-indication to X ray therapy. Dr. Finzi had treated over 100 selected cases during the last 11 years, of which only one had been a complete failure and one a partial failure. The advantage over operation was that the patient need not lie up. When the treatment ended the patient was well, and there was no prolonged convalescence. Radiation sickness could be avoided if each treatment was spread over three or four days, and repeated three to six times at four-weekly intervals.

Dr. G. BLACKER was interested in the paper by Dr. Eden and Mr. Provis, inasmuch as he himself had abandoned the use of X rays years ago. In a few cases he used radium, but he advocated complete removal of fibroids larger than a four months pregnancy, as well as those complicated by degeneration, pressure symptoms, pelvic inflammation, or pain. Radium, in Dr. Blacker's opinion, combined all the advantages and had none of the disadvantages of X rays. The intra-uterine application of radium eliminated the risk of burns and late sequelæ such as telangiectases, which might occur many years after treatment by X rays. Moreover, it entailed a preliminary exploration of the uterus, a valuable safeguard against missing a malignant case. Dr. Blacker had treated 40 cases in all with radium—about 12 for small fibroids and the rest for hæmorrhage at the menopause, using 100 mg. for 24 hours. He had also used radium in patients as young as 29 to cure menorrhagia, when curetting had failed. With a dose of 2000 mg. hours he obtained 9 months' amenorrhœa, during which time anæmia could be treated and another dose of radium given later if found necessary. The results published in America were on a much larger scale than in this country. Leda J. Stacy of the Mayo clinic had reported 600 cases and H. A. Kelly 180 cases of fibroid tumour, of which 171 had been cured. Nine had had to be operated on and no dense adhesions were found. Dr. Blacker then described the technique used by him. After dilatation and curettage he inserted a tube of 100 to 120 mg., protected by a screen of 2 mm. of lead and 3 mm. of silver, into the uterus. The treatment took 24 hours only and the patient was laid up for only two or three days. He disagreed with Dr. Finzi in so far that he found the first period tended to be excessive and therefore he chose a time midway between periods for treatment. There was no danger at the time, but if a too large dose were given late sequelæ might supervene. A purulent discharge started in one case some months after treatment and a septic arthritis ensued. The radium acted directly on the uterus, causing an obliterative endarteritis: the artificial menopause was thus produced by direct action on uterine tissue. Of Stacy's cases some were quite young, and the dosage in these cases was reduced to 30 or 60 mg., or the time of exposure lessened. It had been said that a monster was likely to result if X rays were used during pregnancy, but of the six cases of pregnancy Stacy's collection three had had healthy children. Radium therapy was short, certain, and efficient; certainly it was expensive, but so, Dr. Blacker understood from patients, was treatment by X rays.

Dr. LOUISA MARTINDALE advocated intensive X ray therapy in a large percentage of cases of fibromyomata of the uterus. Since January, 1914, when she had first started X ray treatment, she had had 136 cases of fibroid uterus under her care. Of these, she had treated 56 by hysterectomy, 5 by myomectomy, and 43 by X ray therapy. In 5 cases hysterectomy was performed after X ray treatment. In 41 per cent. of cases, therefore, of uterine fibroids requiring treatment she had definitely chosen radio-therapy, and since probably 9 of the hysterectomy cases could equally well have been treated by X rays, the percentage of cases suitable for radiotherapy was really nearer 50 per cent. The technique adopted was that studied by Dr. Martindale in 1912 and 1913 in the gynæcological clinic of the Freiburg University under Krönig and Gauss, with slight modifications due chiefly to the use of a Coolidge tube since 1919. She had already published the details of the technique, which, briefly, consisted in the use of much cross fire through 18–22 ports of entry, carefully marked out on the patient's abdomen and sacrum. The tube was tilted so that the central ray through each square area reached the ovaries. Dr. Martindale gave one series of two treatments, irrespective of periods, on two consecutive days once in three weeks; she worked with a very hard tube, at least 9 inches, with 4–5 milliamps, and used a filter of 3 mm. of aluminium. The protection of the patient was extremely thorough, and the dosage was measured by Kienboeck's strips, which the nurse in charge developed at a specified temperature, in a standard developer, for a specified time. Dr. Martindale said she thus had accurate and permanent records of the dosage employed for each patient. She had never seen any bad effects, never a burn, and only twice any pigmentation. In 5 cases there was some "Röntgenjammer." She considered the ideal cases for X ray treatment those in which the patient's age is between 40 and 50, the tumour not bigger than a six months pregnancy, and the fibroid interstitial, the chief symptom being menorrhagia. In such cases from four to six treatments would effect a cure—that is, a lasting amenorrhœa, an improvement in the general condition, a shrinkage of the tumour to at least half its original size, and a climacteric free from uncomfortable symptoms. Cases complicated by grave heart or lung disease, exophthalmic goitre, asthma, or any other serious disease did well with X ray therapy, and in such cases Dr. Martindale had used this treatment even when the tumours reached far above the umbilicus. She chose operative treatment: (1) for submucous, subperitoneal, or pedunculated fibroids; (2) for cases of carcinoma of the body (sometimes a diagnostic curetting was done before treatment was decided on); (3) in all cases of doubtful diagnosis. In 4 cases a fresh series of X ray treatments had to be given after an interval of some months; in 1 case, after ten months' amenorrhœa, there was one period; in another after seven months. In another there was slight metrorrhagia, which subsequently cleared up. In the 5 cases in which a hysterectomy followed X ray treatment sections were made of the uterus and ovaries. In 1 case (9 treatments, 2261 X, Kienboeck) the pathologist reported:—

> Section shows a very cellular fibroid, there is no sign of inflammatory change, and degenerative changes are also absent.

In another (7 treatments, 2390 X):—

> The large fibroid has been cut and shows the usual muscle bundles in a fibrous stroma. There is no obvious increase in the amount of fibrous tissue or other degenerative change. The ovary also shows all the normal structures, including a recent corpus luteum, so that in this case the X rays have not apparently destroyed the ovarian function. No evidence of any malignant growth.

In another case 4 treatments (1250 X in all) cured the menorrhagia, but the year after the patient developed gastro-intestinal trouble and became emaciated, with ascites and symptoms of chronic intestinal obstruction. The uterus was very hard and immovable. A total hysterectomy was performed. No adhesions were found; the fibroid had undergone calcification in some areas, and the intestines were covered by small white spots. The patient died ten days after, and the post-mortem showed—

> Dense matting of all intestines and masses of malignant growth of omentum, stomach, and mesentery; there were numerous hard lumps like sago grains. Sections showed a malignant growth, probably endotheliomatous in origin, and apparently primary in omentum.

Dr. Martindale described one other case in which hysterectomy had been successfully performed after menorrhagia had been relieved, but pressure symptoms remained troublesome. In all the cases of her series, except those mentioned, Dr. Martindale said that the patients had done extremely well. She felt that though the improvement in health was doubtless primarily due to the cure of the anæmia, there was some other factor at work. She had recently corresponded with or seen all her cases except two, and their reports as to their energy and well-being had suggested strongly that a woman who has undergone X ray treatment ages less quickly than one who has suffered a hysterectomy.

Dr. **S. Gilbert Scott** said that larger openings would, in his opinion, have given even fewer failures than those described by Dr. Eden, because ovaries were sometimes tucked away and impossible to locate. Krönig himself had given up the technique of many openings. There was no reason to treat fibroids as different from any other deep abdominal tumour, and no need to use enormous doses. It was now some 18 years since the first attempts were made to apply X rays as a means of inducing an artificial menopause and of relieving symptoms where fibrous and myomatous tumours of the uterus were present. Dr. Scott well remembered how sceptical English radiologists were when this method of treatment was first advocated by continental workers, but practical experience soon proved what a valuable therapeutic agent was at hand. Remarkable results had been achieved, even in those days when apparatus and technique were undeveloped. Gynæcologists had been as sceptical as radiologists and, owing either to conservatism or prejudice, little headway had been made in this country until recently. Dr. Scott congratulated the section on having taken the matter up seriously; the conjoint discussion of radiologists and gynæcologists at Cambridge last year showed the keen interest now being taken in the subject. Dr. Scott was disappointed that Dr. Eden and Mr. Provis did not record 700 instead of 70 odd cases, as it was only from large numbers that any definite rules could be laid down as to which cases are suitable and which unsuitable for X ray treatment. If the results were to be satisfactory, the gynæcologist or radiologist must have absolute control over his technique, dosage, &c. Slipshod methods were not permissible. Moreover, the gynæcologist's opinion was essential before the radiologist could give his as to the suitability of a case. The ideal method was for both specialists to see the patient together in consultation, as was the custom of Dr. Williamson and Dr. Finzi at St. Bartholomew's Hospital. Dr. Scott wished to emphasise the extraordinary control to be obtained over the common menstrual disturbances, such as dysmenorrhœa. The age of the patient did not matter, as there was no risk whatever of sterilisation provided the radiologist had full control over dosage and technique. It was easy to coax the periods back to normal in most cases without the necessity of stopping even one, and it was a mistake to think that to obtain results in these cases, sterilisation, whether temporary or permanent, was necessary. The technique was somewhat different from that used in fibroids—less intensive, as the ovaries were very sensitive. One puzzling point was the occasional early relief of bladder pressure symptoms, at a time when fibroids had not shrunk to any appreciable extent. Dr. Scott agreed with Dr. Martindale that adhesions were not serious in uncomplicated cases; they might result from the disease that was being treated.

Dr. **Herbert Williamson** said he was a firm believer in treatment by X rays and radio-active substances for malignant disease as well as for fibroids. At present such treatment was largely empirical and not scientific, mainly owing to the difficulty of measuring dosage and of estimating how much radiation was lost before reaching the organ or tumour. These difficulties would be overcome in time. He thought it would have been more helpful if the dosage in Dr. Eden's paper had been measured in either H or X units instead of by time of exposure only. With Dr. Finzi, Dr. Williamson had treated 15 cases in the last year and a half, including fibroids, chronic metritis, and so forth. All cases had been curetted and microscoped first; this was of great importance. All but two cases were highly successful, and no untoward results had occurred. On the other hand, it must be remembered how satisfactory were the operative results in the treatment of fibroids, and the ovaries were thus preserved. Dr. Williamson excluded from X ray therapy cases under 40 or those in whom the tumour was very large, or degenerating, or could be enucleated; also where a condition of inflammation or malignancy, pressure symptoms, an ovarian tumour, or pregnancy existed. Grave anæmia was also a contra-indication, but transfusion made all the difference to these cases. In three of his patients, young women under 35, severe chlorosis had followed X ray treatment. Dr. Williamson could not agree that the operation was as easy after as before this treatment. In three cases he had found troublesome adhesions and a cartilaginous condition of the tissues. In two cases of fibroids (red degeneration) these were found on operation in an almost sloughing condition, and the patients were very toxæmic. In another case of chronic metritis treated by X rays with apparent success, six months after treatment a discharge of pus containing *B. coli* began. In three weeks it became blood-stained. Microscopical examination of results of a diagnostic curettage were doubtful, but on hysterectomy a carcinoma of the body was found. As to Dr. Blacker's remarks on the use of radium in young women, Dr. Williamson had tried 25 mmg., filtered with a platinum screen, with the usual exposure and also 1 mmg. for 24 hours, but had had no result, and he therefore thought this treatment could not yet be relied on.

Dr. **Cuthbert Lockyer** thanked Dr. Eden and Mr. Provis for the help their paper would give to other workers in this field. Their experience had proved the value of X rays. He asked what percentage of the total number of fibroids the authors considered suitable for X rays. Dr. Martindale had suggested 39 per cent. at Cambridge, and her optimism had now increased to 50 per cent. Why did the authors not express their dosage in X units? Dr. Lockyer suggested as possible explanations of Dr. Eden's unfortunate case: (1) An ascending infection; (2) ulceration following an injury to the bowel caused by X rays; (3) an unrecognised condition of pelvic inflammation existing from the first.

Mr. **T. G. Stevens** described the case of a patient who had had X ray treatment for uterine hæmorrhage due to fibroids. Complete amenorrhœa had resulted, but on operation four years after a large sarcoma was found extending from the external portion of the side of the cervix. He brought forward the case, not from any conviction that the sarcoma resulted from the treatment, but merely to point out that the method was still at the experimental stage and that it was still questionable what late sequelæ might occur.

Dr. **Agnes Savill** said that she now had the abdomen divided into six areas, and each part got one dose. Another excellent method of treatment which should not be forgotten was ionisation of the uterus. Dr. Savill quoted cases in which this method had been very successful.

Reply to the Discussion.

Dr. **Eden**, in reply, was glad to find unanimity among all of the speakers, with the exception of Dr. Finzi, as to the class of tumour suitable for this treatment. He agreed with Mr. Stevens as to possible remote after-effects. In reply to Dr. Blacker, Dr. Eden said he had seen no evidence of late skin changes. He had seldom seen Dr. Blacker so enthusiastic as he appeared to be over radium treatment. The difference was that radium treatment was really operative, involving a curettage and an anæsthetic, and sometimes even a repetition of the latter. With X ray therapy the patient avoided operation, and it was often used *because* operation had been refused. Dr. Eden *did* not agree with Dr. Williamson and Dr. Blacker about the value of a diagnostic curettage. The uterine cavity was often distorted when fibroids were present and could not be satisfactorily curetted. Careful observation of symptoms would be more use in the recognition of malignancy. Dr. Eden had found no clinical evidence of adhesions at operations after treatment. If Dr. Scott could coax periods in young women back to normal Dr. Eden trusted he would give mankind the benefit of his experience without delay.

Mr. PROVIS said that the omission to state dosage in terms of units was deliberate. What proof was there that the ovary actually received any particular dose? In the use of Kienboeck's strips as indicator the solution must always be of accurate temperature, and this was difficult to achieve. It was much safer therefore to speak of length of exposure. It was imperative that the technical side of the treatment should be thoroughly mastered. As to radium therapy probably the gamma ray from a hard tube was the same as the active agent in radium therapy. Whether the same control could be established was doubtful. Mr. Provis had seen one patient seriously knocked out after radium treatment. As to Krönig having given up the Freiburg method, this was probably true because Krönig was dead.[1] The great advantage of small openings was their safety. It was hardly right to deal with dysmenorrhœa in young women in the present state of our knowledge. No effect might be seen for some time, and suddenly amenorrhœa might be produced without warning.

SECTION FOR THE STUDY OF DISEASE IN CHILDREN.

EXHIBITION OF CLINICAL CASES.

A MEETING of this section of the Royal Society of Medicine was held on Jan. 28th, Dr. F. S. LANGMEAD, the President, being in the chair.

Dr. J. PORTER PARKINSON showed a case of

Patent Ductus Arteriosus

in a girl, aged 7 years, who had been admitted to hospital for cough and spitting of a small amount of blood which apparently came from the throat.

The family history was unimportant. The child had never been strong; she had had influenza, measles, and chicken-pox, and in 1915 had spat up a little blood, which had continued for about two months; the attacks of hæmoptysis had recurred each following year, and between them she had been well. She was a child of low intelligence with a Mongolian type of face. The cranial circumference was 47 cm. There was no cyanosis or clubbing. The apex of the heart was in the fifth intercostal space, ½ inch inside the nipple line. The right border of deep dullness was ¼ inch to the right of the right border of the sternum, the left border of dullness was continued upwards in the third and second intercostal spaces, gradually approaching the sternum. In the second intercostal space near the sternum could be heard a loud harsh murmur continued through systole into diastole, the murmur being heard, though less loudly, all over the cardiac area, in the vessels of the neck, and at the back of the chest, especially on the left side. The pulmonary second sound was not accentuated. The lungs and abdomen appeared normal, and there was no enlargement of the liver or spleen.

The case was regarded as typical of patency of the ductus arteriosus. Both percussion and a skiagram showed the enlargement of the heart to the right, and Gerhardt's line of dullness prolonging upwards the dullness of the heart, and due doubtless to dilatation of the pulmonary artery. The only unusual sign was accentuation of the pulmonary second sound. This he suggested might be due to patency of the inter-auricular septum.

Dr. F. PARKES WEBER said that there was present in this case the typical murmur of patent ductus arteriosus to which attention had first been drawn by Dr. G. A. Gibson, of Edinburgh. It had lately been recorded, however, that a number of cases had been shown to be of patent ductus arteriosus in which there had been no murmur of the Gibson type. A recent writer had suggested that this murmur was never found in simple ductus arteriosus, but only when the condition was complicated by inflammations and vegetations. An observer, however, had already stated that a patient had had the typical murmur apart from inflammation. —The PRESIDENT said that an interesting point was whether such a murmur was necessary in patent ductus arteriosus. He thought that there were cases of this condition in which only a loud systolic murmur was heard, but the Gibson murmur was, no doubt, more characteristic.

Sir THOMAS HORDER showed a case of

Idiopathic Dilatation of the Alimentary Canal

in a boy, aged 6½ years, who was otherwise quite healthy. The abdomen was large and the costal margin was symmetrically expanded. The enlargement was uniform, the percussion note was tympanitic, there was no enlargement of veins or ascites, and no rhythmical peristalsis. The temperature was normal, there had been no vomiting or sweating, and there was no cardiac or renal disease.

The abdomen had always been large, but two years ago it had become larger. The doctor in attendance was satisfied as to the absence of tuberculous peritonitis, and treated the condition by massage and exercises, with improvement. One month ago the abdomen had again increased in size, and the enlargement had been said to be more noticeable after any nervousness or excitement; there was then also slight pain. Weight had not diminished. The boy passed much wind per anum, but did not eructate. Skiagrams were shown, taken after an opaque meal. There was considerable dilatation of the stomach, which lay athwart the abdomen. It had not dropped, but was clearly atonic. The pyloric segment lay at the top of the right iliac fossa. There was no conspicuous delay in the passage of the opaque meal. After 4½ hours the stomach was empty, and the cæcum, which was dilated, was becoming filled. At the end of six hours the cæcum was packed. At the end of eight hours the cæcum was full, and the sigmoid fairly full and lying to the right of the mid-line. At the end of 25 hours some of the meal still remained in the cæcum and there was a good deal in the sigmoid. The transverse colon was not dilated, but seemed contracted and spastic in places. He thought that a large, dilated, and atonic stomach, a dilated cæcum and ascending colon, and a somewhat dilated sigmoid were present. There was no constipation, the bowels acting two or three times in the 24 hours.

The case did not conform to any of the described types of idiopathic dilatation.

Dr. PARKINSON said that there were no symptoms or signs except those by X rays. At that age slight dilatation of the stomach and of the cæcum was not unusual, especially if the diet were indigestible, as it was likely to be when the mother was over-careful and indulgent, as in this case. All that would probably be necessary would be to regulate the diet carefully.—Dr. G. DE BEC TURTLE thought that the case belonged to a group in which there is spasm of some part of the alimentary tract—in this case in part of the colon. With regard to treatment, he would advise massage and await events. In these mild cases the spasm was often overcome by simple measures and the patient got well.

The PRESIDENT showed a case of

Rheumatoid Arthritis

in a boy aged 6 years. When first seen at 1 year and 9 months there was considerable swelling over the dorsa of the hands and feet not limited to the wrists and ankles, a combined macular and papular rash, and areas of erythema over the breast and arms, and offensive motions. He had regarded the rash and œdema as toxic in origin and connected with the offensive stools, but treatment directed to the latter proved valueless, the rash and œdema persisting, and the boy was admitted to hospital. About this time he developed fixation of the neck, which was very painful and caused cervical caries to be suspected, but this was negatived by X rays. Dr. W. S. Colman, under whose care the child was while in hospital, made the tentative diagnosis of rheumatoid arthritis, which subsequently proved to be the explanation. Later the swelling of the hands became more localised to the carpal and tarsal joints.

After discharge from hospital, he remained pale and looked ill, the joint swellings varying considerably from time to time. The only treatment which appeared to benefit him was thyroid in small doses, and under this he gradually improved. In August, 1917, he was again admitted for fever, breathlessness, and further painful swelling of the joints and painful stiffness of the neck. Thereafter he again improved, though he did not lose the joint swellings and stiff neck. In January, 1920, after a "cold," he again became feverish, and complained of pain in the left ankle; the joints became more swollen and a purplish macular rash appeared on the knees. On admission again his temperature was normal, but pulse 156, and pallor was obvious. About the wrists and ankle-joints were symmetrical periarticular swellings reaching from the lines of these joints to the metacarpo- and metatarso-phalangeal joints. The swelling was limited to the dorsal surfaces. Glands were enlarged in the axillæ and groins. A purplish erythema affected both forearms. Besides the tachycardia a slight systolic murmur, limited to within the apex, was audible. The spleen was palpable, reaching about one inch below the ribs.

---

[1] THE LANCET, 1917, i., 841.

With regard to possible sources of infection, there were two carious teeth, and a nasal discharge; the urine was sterile and the stools yielded no lactose-fermenting organisms and no excess of Gram-positive organisms (Dr. D. N. Nabarro). An X-ray examination (Dr. Ironside Bruce) showed "marked general bony changes in the tarsus and carpus which showed advanced ossification as compared with the metatarsus and metacarpus; some signs of localised destruction of bone." Under observation in hospital he ran an irregular fever at intervals of two or three days, his temperature sometimes reaching 102° or 103° F. and subsiding within an hour or two. The rises of temperature were associated with no subjective signs, but a patchy pink erythematous rash appeared on the chest. A vaccine was prepared from the predominant organisms of the stools (*B. coli* and streptococci), but produced neither local nor general reaction to 25 millions of each on two occasions. Later the rash spread to the arms and thighs both on their flexor and extensor aspects, the patches of erythema varying from the size of a pea to that of a sixpence. Another dose of the vaccine (50 millions of each organism) produced again no kind of reaction and failed to affect the disease, the stiffness of the neck and the swelling of joints becoming more marked and an irregular temperature and slight tachycardia persisting. A culture from a septic tooth grew only *Micrococcus catarrhalis* and streptococcus, and a vaccine prepared from them also failed to produce a reaction. Owing to infection in the ward the boy was discharged after three months, in April, 1920. He had since been attending the out-patient department and has again improved with thyroid, the joint swellings and fixity diminishing, the spleen becoming smaller and no further rash having appeared. There was still some stiffness of the neck.

The case was shown to illustrate: (1) The early œdema, resembling toxic œdema, of rheumatoid arthritis. (2) The association of a rash with each recrudescence of joint swelling and pain. (3) The value of thyroid in certain cases of the disease.

Dr. R. LLEWELLYN JONES said that he had found thyroid to be of most value in adult cases with local syncope of the fingers, such as made it difficult to distinguish the condition from Raynaud's disease. His experience corroborated that of the President. He considered that the term "rheumatoid" should not be applied to these cases. He would prefer to reserve that term for atrophic cases with scleroderma. This was undoubtedly a case of Still's disease; he would prefer to call it "infective arthritis."—Mr. H. A. T. FAIRBANK referred to a case in which an operation had been performed and the ileum joined to the colon, but no benefit had resulted. He had seen the child again, and found that the hips were markedly affected and the joints stiff. X ray examination had shown much alteration of the articular surfaces. Dr. Still said that it was not similar to those which he had described, but was an osteo-arthritis with destruction of bones.—Dr. WEBER asked the President whether he had seen these cases associated with psoriasis, for the two were often associated in adults.—The PRESIDENT, in reply, said that he had not recognised the association with psoriasis in childhood. He agreed as to the diagnosis of Still's disease, and, indeed, used the term "rheumatoid arthritis in children" as synonymous with Still's disease.

The PRESIDENT also showed a

Case of Obesity.

The patient was a boy, aged 11½ years, who was admitted to hospital in February, 1920, for "excessive fatness" which had been gradually increasing for one year. He was the eldest of four children, the two youngest of whom had died, one of broncho-pneumonia, the other of diarrhœa and vomiting. His only illnesses had been a severe attack of "diarrhœa and vomiting" when aged 1 year, after which he was greatly wasted, and poliomyelitis, which was not detected until he started to walk at 1 year and 5 months. The atrophy and weakness of muscles was confined to the right leg.

At the age of 9 the boy was a thin weakly child, pale and ill-nourished; at 9½ he appeared well-nourished, at 10 he weighed 5 st. 8 lb. and four months later 6 st. 12 lb. The excess of fat appeared first on the trunk. He suffered every three or four days with nausea and severe frontal headache. When he came under observation his appearance was that of a boy of 13 or 14, rather than of 10½. There was general excess of fat, more marked on the trunk, where it was thrown into folds. The breasts showed gynæcomastia. The genitals were normally infantile. Teeth were normal. No precocious development of hair. Supraclavicular fat not disproportionately excessive. Intelligence good and no abnormal nervous signs (except those of poliomyelitis). The urine was not increased and contained no sugar. He was given 120 g. of sugar after the bladder had been emptied, and three hours later passed urine containing 0·2 per cent. of glucose. An X ray examination of the skull was negative.

Treatment by pituitary extract was given, 8 minims of pituitrin (i.e., a 20 per cent. extract of the posterior lobe) being combined with an extract of anterior lobe of an ox's pituitary (each dose containing 5 gr. of the dried lobe). This was injected into the buttock. At first four doses were given in five days and led to a decrease in weight by 2 lb. 5 oz. When this was followed by weekly doses the weight steadily increased again, and when discharged, after one month, he weighed 12 oz. more than on admission. The initial loss of weight was regarded as probably due to the distress, sleeplessness, and loss of appetite caused by the frequent injections. When next seen in out-patient department in March, 1920, he weighed 7 st. Thyroid (2 gr. daily) was given, and on Sept. 11th the weight, after slight fluctuations, was still 7 st. A slight illness then caused it to drop to 6 st. 10½ lb.; the thyroid was discontinued, and a fortnight later he had gained 2½ lb. Thyroid (3 gr. daily) led at first to a decrease of weight, but after a month it again increased. He was now taking 4 gr. daily. His last weight was 6 st. 9½ lb., which was less by 2½ lb. than in January, 1920. He was more usual in appearance and had grown considerably. There was no evidence of gonadic disability.

The case was regarded as possibly one of subnormal activity of the thyroid gland, and the question was raised as to whether the obesity often met with after recovery from severe inanition in children was so explained. He thought that these cases were often called dyspituitarism on insufficient evidence.

Dr. E. A. COCKAYNE said that cases of this kind which he had seen during the past year or two had shown no evidence of hypopituitarism, and those examined had shown no abnormal sugar tolerance, and the X ray examination had been negative. He doubted if the slight loss of weight after thyroid was an evidence of thyroid deficiency.

Dr. L. W. BATTEN showed for Dr. H. MORLEY FLETCHER a case of

Scleroderma with Sclerodactylia in a Child with Infantilism.

There had also been some joint changes leading to fixation. The muscles were hard and suggested myositis fibrosa, which with the scleroderma contributed to the limitation of movement at the joints. An especial feature was the presence of nodules, situated both over bony prominences and in loose tissues, as in the subcutaneous tissue of the abdominal wall. Some of these were freely movable, others attached to deeper structures. X rays and examination after removal failed to show any calcareous change in them, and microscopically they consisted of fibrous tissue.

Dr. WEBER considered the case to be one of the sclerodactylia form of scleroderma, associated with some remarkable features: (1) the fibrotic changes were not confined to the skin, but had led to stiffness of some of the small joints and possibly also affected muscles, producing a mild condition of myositis fibrosa; (2) infantilism; and (3) the presence of subcutaneous nodules. He felt sure that the nodules, from their appearance and distribution, were of the type of rheumatic nodules not associated with a cardiac lesion. He asked whether the child had been subjected to cold or neglect, for it was possible in sclerodactylia, when affecting young children, that neglect (especially with regard to feeding) and exposure to cold had an effect.—The PRESIDENT said that there was a group of cases, as described by Dr. J. A. Nixon, in which, as well as scleroderma and sclerodactylia, there might be similar changes in muscles, joints, and even in the pleura and pericardium. The present case reminded him of one which he had shown in which there was also myositis fibrosa and scleroderma, sclerodactylia, and fixation of joints, which were well marked within a few weeks of birth, and were probably congenital in origin. An unusual feature in the case now shown was the nodules, which, though resembling those of rheumatism to some extent, he thought were not rheumatic, and were different both in shape and distribution. The nodules reminded him more of calcinosis, which might also be associated with a condition of skin resembling scleroderma, but that was not apparently the explanation in this case. He felt that there was some connecting link between these various conditions.—Mr. B. WHITCHURCH HOWELL spoke of the necessity, from the point of view of practical treatment, of coaxing the joints into the optimum position of utility.

Dr. W. J. PEARSON showed

A Case for Diagnosis.

The patient, a child aged 5 years and 11 months, first attended hospital a year ago for wasting of six months' duration. There had been slight puffiness of the eyes with loss of appetite for two months. A cough was associated with some expectoration; there was no fever. A trace of albumin had been found in the urine on one occasion. The liver reached two and a half finger-breadths below the costal margin; the spleen was not enlarged. The child was undersized for its age, but was bright and intelligent. The middle portion of the trunk resembled that of a developed woman, but the shoulders were comparatively infantile. There was considerable increase of subcutaneous tissue all over the thorax and thighs, but especially noticeable over the abdominal wall. The abdomen was distended. The Wassermann reaction was negative and X ray examination showed no epiphyseal changes.

Dr. WEBER suggested the possibility of suprarenal tumour with which obesity of this form was sometimes associated. In such cases, however, there was usually sexual precocity and hypertrichosis.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.

A MEETING of this society was held at 11, Chandos-street, London, W., on Jan. 21st, with Professor W. J. R. SIMPSON, the President, in the chair.

A paper was read by Lieutenant-Colonel C. A. GILL, I.M.S., entitled

The Influence of Humidity on the Life-History of Mosquitoes and on their Power to Transmit Infection.

Hippocrates and many early classical writers had observed the association of malaria with the humid atmospheres prevailing around swamps and marshes. In modern times the importance of humidity was referred to in treatises on malaria, but without regard to its precise significance. Relative humidity—i.e., the amount of moisture in the air expressed as a percentage of that required to cause saturation—he pointed out, was subject to marked variations with change of temperature, the two factors bearing an inverse ratio to each other, and their close interdependence necessitated both being taken into account in determining the influence of either on malaria.

Colonel Gill proceeded to describe experiments which had been conducted with *Culex fatigans* and bird malaria (*Proteosoma grassi*) with reference to the effect of varying degrees of humidity on the length of life of the culex and on its power to transmit bird malaria.

The mosquitoes were placed in a series of incubators at 27° C., and their duration of life was determined under different degrees of relative humidity; in other respects the conditions to which the various batches of insects were exposed were identical after feeding them the previous night on an infected sparrow. Each morning the dead mosquitoes were removed and counted, and dissections were carried out to ascertain the number of oöcysts which had developed in the midgut. Records of humidity and temperature were carefully kept through readings of the wet and dry bulb and maximum and minimum thermometers. Variations in humidity were secured by placing small wet sponges in the incubators and by means of calcium chloride and dilutions of sulphuric acid. Special care was taken to maintain the incubators and constant temperature.

The results of his experiments were briefly summarised, and showed that *Culex fatigans* was invariably killed within five days with a relative humidity of 45 per cent. or less, but death rarely occurred within ten days with a humidity between 65 and 75 per cent., whilst 80 per cent. humidity was even more favourable to life. As with the effect on the culex, so with the development of *Proteosoma grassi*, the influence of these conditions of temperature and humidity proved constant in the regularity of appearance and maturity of the oöcysts found in the midgut of the culex, irrespective of the degree of relative humidity, save that with low humidity (45 per cent. or less) the desiccation of the mosquitoes prevented any further examination. There was, however, apparently a close relationship between the number of oöcysts in the midgut of the mosquito and the number of parasites in the blood of the sparrow, provided the count of the latter was made on the day of feeding. From the results of these experiments he had concluded that a mean relative humidity of not less than 48 per cent. at a temperature of 27° C. was essential to the existence of *Culex fatigans* for a period of five days, and that a lower degree of humidity prevented the transmission of bird malaria owing to the death of the insect host; also that the degree of infection or rate of development of the sexual parasite in the mosquito was not directly influenced by relative humidity. Examples based on observations in Lahore were quoted as to the influence of humidity on the length of life of the culex and the effect of atmospheric changes on the habits of mosquitoes during the course of the day under natural conditions, the preference for the more humid shelter within the house in the heat of the day, and the avoidance of it when night fell. Under both experimental and natural conditions feeding habits of mosquitoes appeared to be governed alike by the degree of relative humidity, for failure to feed occurred in experiments with a daily mean humidity under 40 per cent., whilst successful feeds were obtained when the relative humidity was over 50 per cent. Such influence would seem to account for the disappearance of the mosquito in the Punjab during the intense dry heat of June and for its return and commencing to feed after the first monsoon. During hibernation, when exposed to low mean temperature and high mean relative humidity, insects were known to live for several months. Although his observations had been confined to *Culex fatigans*, he considered it justifiable to assume that his conclusions were applicable in principle to all mosquitoes and to the significance of their habits of selecting special types of shelter favourable to their survival.

The Rôle of Temperature.

Low temperature combined with high degrees of relative humidity was regarded as not unfavourable to the existence of the culex, although at 10° C. the insect became sluggish and showed no desire to feed. At 26° C., however, and with high but *not* with low degrees of humidity, there was marked activity, readiness to feed, and rapid development of eggs, whereas at 40° C. *Culex fatigans* died quickly in contrast to some Indian anophelines. Recent observations made at the London School of Tropical Medicine, and also by Roubaud, led to the conclusion that temperature exerted a direct effect on the malarial parasite in the mosquito; low temperature inhibited the growth of the oöcyst, and within certain limits its rate of development was dependent on the mean temperature. In the case of *Culex fatigans* length of life was compatible with a wide range of temperature, but vitality was reduced at low temperature. He consequently regarded the mechanism of malarial infection as being in no small degree influenced by and dependent on the combination of the factors of temperature and humidity, and he emphasised the importance of ascertaining the optimum conditions of these factors and the range between the limits favourable to the transmission of infection. Such information would serve to elucidate certain points bearing on the endemiology and epidemiology of malaria. As examples, he mentioned that though the distribution of anophelines in the United Kingdom was widespread, indigenous malaria was much restricted, and he subsequently showed that this was due to its confinement to areas where favourable conditions of temperature and humidity prevailed. Similarly, he explained *paludism sine malaria*, the concurrence of anophelines and human carriers with the absence of fresh infections. He also regarded *malaria sine paludism* or the occurrence of new infections in localities where there were few anophelines and human carriers, provided there was a period of potential infection, as attributable to favourable influences of the two factors concerned. He claimed that the rôle of meteorology was a subject of considerable importance, and that the practical bearing of the information it afforded was the possibility, so long as the required meteorological data were available, of determining the season of the year and duration of the period during which malaria could normally be acquired in any particular area. It seemed probable, indeed, that with the knowledge provided by the meteorological conditions in the United Kingdom less importance could be assigned to anti-mosquito measures in the particular areas where conditions were known to be unfavourable to the transmission of malarial infection.

Discussion.

Dr. A. G. MACDONALD was of opinion that warmth and humidity should not be dissociated in a consideration of the subject of the incidence of malaria; temperature had a universal influence, humidity a local influence. He referred to the states of atmospheric temperature and humidity in Mesopotamia and Singapore. In the former region hospital admissions for malaria did not fluctuate during the months of low humidity, but variations in the admission-rate occurred in winter when temperature was lower. There was a reduction of infection in June and July, months of low humidity. Colonel Gill's observations had shown the effects of low humidity and influence of temperature on the development of the parasite. These factors had also an important bearing on the question of preventive measures. The minimum and maximum of conditions favourable for the development of the plasmodium in the mosquito were points requiring investigation; there was also the necessity of ascertaining facts bearing on the distribution and proportion of malarial cases in relation to the factors under discussion.

Dr. B. BLACKLOCK regarded Colonel Gill's conclusions as being in advance of the results obtained in his experimental work. Colonel Gill had proved that when the relative humidity was reduced below 45 per cent. the culex died, and that, with the survival of culex, development of *Proteosoma grassii* proceeded in a regular manner. What bearing had these results on the anopheles and malaria? As 14 of the culices had died and 16 had survived in the course of the experiments, he thought it probable that other factors than humidity would have to be taken into account in connexion with the survival of anopheles and the cycle of development of the parasite. Preventive measures could not yet be guided by Colonel Gill's observations. He criticised the acceptance of some of the mean readings given of relative humidity as inconsistent.

Dr. P. H. MANSON-BAHR stated that the death of the 14 culices could be attributed to the unfortunate accident of starvation and thirst in these particular experiments, and not to the effects of humidity and temperature. He considered that many minor factors besides humidity and temperature had effect on the development of the oöcyst in the mosquito.

Dr. C. M. WENYON described the difficulties of keeping culices alive; if they were kept too moist they died of enteritis, if too dry they died from desiccation. He referred to the dryness of Baghdad and the activity of mosquitoes during the hot months, attributing their survival under natural conditions to their habit of congregating on the water-jars during the heat of the day for the purpose of obtaining necessary moisture.

Mr. A. BACOT attributed the death of the mosquitoes in the experiments to heat-stroke, and regarded the circulation of air in the incubators as an important factor in keeping the insects alive. He inquired as to what they were fed on during the seven days' period, and referred to the favourable influence on mosquito life of isothermic conditions in certain localities, such as the Essex mud flats, and in explanation of their selection of similar haunts.

Sir RONALD ROSS quoted from past observers as to the influence of humidity and temperature, and gave his own experiences of the effect of high temperature on mosquitoes kept for experimental purposes. There were many variable influences to be reckoned with as producing variations in malaria, and it was not a question merely of humidity and temperature.

Reply.

Colonel GILL, replying, stated that the mosquitoes were fed on raisins, sometimes watered once a day by means of a small moist sponge on the bottle cover when the humidity conditions became low. He quite realised that in his experiments he was only partially dealing with two variables influencing malaria. He did not consider the monthly mean humidity of 63 per cent. for the 8 A.M. reading to be inconsistent; the 50·8 per cent. mean of 24-hourly humidity corresponded with a considerably higher 8 A.M. humidity. *Paludism sine malaria* existed if the temperature was not high enough, as no infection could be obtained. The influence of temperature and humidity on the spread of malarial infection varied according to the particular zone concerned; in England temperature was the prevailing factor, but in the tropics humidity was more concerned, and the importance of local conditions was paramount in determining a high or low humidity.

Colonel Gill exhibited charts showing the variations of relative humidity and atmosphere temperature at corresponding times during the 24 hours and the different months of the year. He also showed under the microscope specimens of the mid-gut of *A. maculipennis* which had been fed on a case of benign tertian malaria and incubated at 22° C. and at a relative humidity of 50·5 per cent. for: (1) Six days, showing development of small oöcysts containing pigment; (2) seven days, showing an increase in size of the oöcysts, but less pigment; (3) nine days, with many oöcysts of the same size as (2), but, in addition, the presence of sporozoites.

Demonstrations.

The following demonstrations were given:—

1. Rickettsia in the Bed Bug, by Mr. BACOT. The passage of *R. lectularia* from generation to generation was described as having been traced through the egg of the bed bug without the intervention of an intermediary host. The bodies appeared as minute coccoid, small-rod, and thread forms, and occurring in true diplo-coccoid form within the cytoplasm of the cell, but not in the nucleus. All the bed bugs examined had been found to be infected, and there had been very few failures in making the smears. Cimex of pigeons and bats were wanted for investigation, to see if they showed Rickettsia bodies, as *Cimex lectularia* did in sheep. Mr. Bacot exhibited specimens of *R. lectularia* of the bed bug in sections of the gut and Malpighian tubules, the cells of which were greatly enlarged, due to masses of the minute coccoid and thread forms; also in smears of the gut, ovary, the organ of Berlese, and the egg of the bed bug.

2. Sigmoidoscopic Diagnosis of Amœbic and Bacillary Dysentery, by Dr. MANSON-BAHR and Dr. A. L. GREGG. By means of the epidiascope coloured drawings were shown on the screen of the appearances, as seen through the sigmoidoscope, of the inflamed and ulcerated mucous membrane of the bowel in amœbic and bacillary dysentery, and of the subsequent polypoid and fibrotic

changes. The demonstration also included drawings of dysenteric ulceration in section, and of the material obtained through the sigmoidoscope from an ulcer showing numbers of *E. histolytica*. The sigmoidoscope was passed round for inspection and the method employed for collecting material from the surface of the bowel was explained. The figures quoted by Dr. Manson-Bahr made clear the great value of this method for the examination of material in the establishment of a correct diagnosis of dysentery cases as compared with the usual investigation of fæces only. Out of 247 examinations made, over 60 per cent. of cases had been verified as amœbic dysentery by the use of the sigmoidoscope, whereas by routine microscopic examination of the fæces *E. histolytica* or its cysts had been found in under 40 per cent. only. Preparation of the patient was necessary by means of a dose of ol. ricini, and by the administration of tinct. opii ♏ xv. four hours before examination. The process was more painful in bacillary dysentery and the amount of pain caused required to be taken note of. It was claimed that the sigmoidoscope provided a rapid and accurate means of diagnosis of dysentery, and of the recognition of unsuspected conditions such as internal hæmorrhoids, syphilitic stricture, and malignant disease of the lower bowel.

LIVERPOOL MEDICAL INSTITUTION.

AT a meeting held on Feb. 3rd, with Dr. J. E. GEMMELL, the President, in the chair, Mr. THURSTAN HOLLAND read a paper on

Some of the Rarer Conditions of Bones.

He showed radiographs of some of the accessory bones of the foot and of the sesamoid bones, and discussed their importance from the point of view of industrial injuries and compensation. He also demonstrated radiographs of six cases in which the bone of Vesalius was present in both feet, and discussed in detail the question of differentiating between the sesamoid of the peroneus, the presence of a true bone, and epiphyses at the base of the fifth metatarsal. Two cases of Köhler's disease of the scaphoid bone were demonstrated with radiographs showing the condition at the time and two years later. The paper concluded with a description of an exceedingly rare condition of the patella in which radiograph appeared to show an epiphysis on the upper and outer sides of both patellæ.

Dr. H. BALME delivered an address on Surgical Practice in China and Recent Developments in Medical Education, illustrated by lantern slides.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

THE annual meeting of this society was held at Manchester on Jan. 21st, when Mr. CARLTON OLDFIELD was elected President for the ensuing year.

Dr. H. BRIGGS showed a specimen of Tuberculous Salpingitis removed from a patient 13 years previously. She was now in perfect health. He was of opinion that inflamed tubes were more commonly tuberculous than was usually supposed.

Dr. W. W. KING showed a specimen of Hydrometra removed from a nulliparous patient. The uterus was the size of a four months' pregnancy, and the obstruction to the outlet of uterine secretions was caused by a small cyst arising in the mucosa of the cervical canal.

Dr. H. CLIFFORD showed a large Ovarian Tumour removed from a girl aged 12 years. The growth was a sarcoma of rapid growth with extensive areas of necrosis.

Dr. W. FLETCHER SHAW described a case where he had removed a large Myxomatous Tumour of the Left Ovary, the other ovary being at the time apparently quite healthy. Twelve months later the patient returned with a large abdominal tumour which, on operation, proved to be a similar growth of the right ovary.

Dr. F. H. LACEY read a paper on Induction of Labour for Contracted Pelvis based on a series of 75 cases, in which the conjugata vera measured not less than 3¼ inches in flat and 3½ inches in generally contracted pelves. The method adopted was that of Krause, but this was supplemented in 29 instances by the introduction of a de Ribes bag. The maternal mortality was, of course, nil, the morbidity 1·3 per cent. 84 per cent. of the children were born alive, and of these 78·6 per cent. were discharged well on or about the twelfth day.

Reviews and Notices of Books.

SCURVY, PAST AND PRESENT.

By ALFRED F. HESS, M.D. London and Philadelphia: J. B. Lippincott Company. 1920. Pp. 279. 18s.

PROFESSOR HESS has published so much interesting and original work on scurvy during the past seven or eight years that it seems high time to have his observations collected and published in book form. This book has now appeared under the title, "Scurvy, Past and Present," a book which is entitled to rank as one of the most important monographs of recent years. Since Lind published his great classical treatise on scurvy in 1753 no book has been written in English on this subject. The war has awakened fresh interest in food-deficiency diseases of all sorts, but Professor Hess had made scurvy his special study before the war had directed general attention to this group of diseases. His observations were undertaken in the Pediatric Clinic at New York. His experiences have been amplified and matured by the opportunities for seeing the disease on a widespread scale amongst adults which the war afforded. He does not hesitate in his conclusion that adult and infantile scurvy are one and the same disease, having an identical pathogenesis. Indeed, we may actually complain that Professor Hess is almost too considerate of unproven or even disproved theories as to the pathogenesis of scurvy. The reader grows a little tired of the discussion on McCollum's statement that scurvy is due mainly to constipation. There was ample evidence to knock the bottom out of this theory; that evidence could have been briefly stated once and the theory ignored afterwards. What really interests us is the description of the work done by Hess and his collaborators.

The prevalence of scurvy among infants in America and England has never been correctly appreciated, and a great debt of gratitude is due to Professor Hess for his splendid array of uncontrovertible facts impressing on us the impairment in infant development caused by minor deficiencies in antiscorbutic vitamine. The arraignment of patent foods for infants has never been more clearly or trenchantly set forth. The scurvy-producing effects of proprietary foods are not entirely attributable to the heating of the milk in the process of manufacture; even more important causative factors lie in the inadequate quota of milk used to make up the day's feeding and in the practice of rendering proprietary foods (with certain exceptions) alkaline in order to prevent acid fermentation of the fat. Antiscorbutic vitamine is peculiarly sensitive to the faintest alkaline reaction, and is completely destroyed by heat. But when associated with an acid it is greatly protected from the destructive effect of heat. This is well exemplified by the tomato, which is strongly antiscorbutic even after it has been canned. As regards the effect of heat alone, it appears intensity of heat is not so destructive as prolonged heating. For this reason fresh milk rapidly dried by the Just-Hatmaker process is not deprived of its antiscorbutic properties. Not only, however, is this vitamine easily destroyed by heat, it is also peculiarly sensitive to "ageing." Ageing has least effect when the food with which the vitamine is associated has been dried. Storing in an alkaline or neutral medium causes it to deteriorate most rapidly, but even in an acid medium its potency soon diminishes. On this point Professor Hess disagrees with the report[1] of the Medical Research Council "that it may be regarded as an axiom that dry or dried foodstuffs will not prevent scurvy." He points out in discussing the relationship between infantile scurvy and rickets that there is no causal connexion between these two diseases, and that the pathological interference with the development of the bones is radically different, although the diseases so often occur together.

It is now being fairly widely recognised that scurvy is often diagnosed as rickets in young children. It is important that this confusion should be stopped. The main criterion in diagnosing incipient or latent scurvy is the response made by an ill-nourished infant to the addition of an antiscorbutic to the diet. Professor Hess includes a most comprehensive review of the literature and of the experimental work on scurvy; some of his suggestions are unusually stimulating, as, for instance, his comment on Ingier's study of the effect of a scorbutic diet in the mother on the fœtus. "In view," he writes, "of the similarity between human and guinea-pig scurvy, we should expect not only miscarriages and still-births to result, but cases of congenital scurvy, especially of the latent or rudimentary type." He does full justice to the work of others, and may be congratulated on having made good use of his opportunity "to gather into one volume the recent advances in this field and to offer to the clinician, to the hygienist, and to the biological chemist a presentation of the existing status of this important nutritional disease."

---

[1] Special Report Series. No. 38.

DISEASES OF THE LUNGS AND PLEURÆ.

Including Tuberculosis and Mediastinal Growths. Sixth edition. By Sir R. Douglas Powell, Bart., K.C.V.O., M.D., F.R.C.P., and P. Horton-Smith Hartley, C.V.O., M.A., M.D., F.R.C.P., Physician with Charge of Out-patients to St. Bartholomew's Hospital. London: H. K. Lewis and Co., Ltd. 1920. With 36 plates and other illustrations. Pp. xx. + 798. 42s.

This book is, on the whole, of remarkable value. The authors have succeeded in bringing the sixth edition well up to date in most respects, and they have also avoided even critical allusion to certain modern views and teachings which show no sign of viability. There are virtues of omission as well as of commission, and the art of discarding requires even more knowledge and judgment in writing a book on tuberculosis than in playing bridge. To judge by several references to research work published only a little time ago, the authors must have put in much eleventh-hour work. It is, perhaps, a pity that in their preface they write: "...... the last word has been said on antiseptic methods in surgery ......," for such assumption of finality is a challenge liable to be stultified by subsequent events, and it is doubtful if "the last word" has yet been said on this or on any branch of science.

In their first four chapters the authors prepare the reader for the pathology to come by a clear account of the anatomy and physiology of the lungs and of the methods of physical examination they have found most helpful. The illustrations supplementing the text are well chosen; some are the more welcome for being old and trusted friends. In the chapter on hæmothorax and gunshot wounds of the chest the experience of the war has been freely drawn on and the work of British and French surgeons ably summarised. Again, in the chapter on asthma the authors show intimacy with recent advances and appreciation of their importance by devoting considerable space to the work of I. C. Walker, John Freeman, and others on anaphylaxis. In the chapter on actinomycosis the authors follow a time-honoured, almost legendary, tradition in recommending potassium iodide in large doses early in the disease. It will be interesting to see whether or not the claims made on behalf of this drug in actinomycosis will survive the storm of criticism already brewing.

In the large section dealing with tuberculosis the authors range the whole world in their lengthy discussion of various climates; but though they take the reader from Greenland's icy mountains to India's coral strand, they do not introduce him to Leonard Hill's kata-thermometer investigations, which have done so much to convert the empiricism of climatology to a rational science. It is probable that at no time so much as the present has the old controversy over the comparative importance of the "soil" and the "seed" in relation to tuberculosis been so acute, and many readers will, no doubt, first turn to the chapter on this subject to see if the authors have come down heavily on the side of the angels or not. They take the view that the consumptive who, properly trained, is willing and able to carry out instructions, is no real source of danger, and should not be shunned as a leper. They record the case of a lady who, dying of consumption at the age of 48, left 15 children. Of these 15, 7 developed phthisis long afterwards. Why did they do so? "It appears to us that the only answer lies in the doctrine of heredity, the inheritance, as it has been termed, of a 'tuberculous diathesis,' rendering the soil of certain family constitutions more suitable for the growth of the bacillus than that of others, so that, when infected with a suitable dose of the virus, such individuals succumb when their more fortunate brethren escape." The authors then proceed to justify this attitude from a biological standpoint, comparing the fastidious selectiveness of the tubercle bacillus with that of the seed of certain plants. They are, however, careful not to repudiate such a popular and comparatively modern teaching as that of "massive infection." It is curious that they have so little to say about the doctrine that pulmonary tuberculosis is in most cases the direct but distant sequel to infection in early childhood. They do, indeed, briefly refer to this doctrine, but only to pass from it to that of heredity and diathesis.

In a discussion of tuberculous meningitis the authors do not refer to the numerous authenticated records of recovery from this disease. Dealing with laryngeal tuberculosis, they reflect the growing tendency to regard it as a condition best treated by silence and general hygienic measures. The free curetting of ulcerated surfaces, as well as the direct application of lactic acid, so popular a few years ago, are referred to only to be politely damned. In the matter of laryngeal tuberculosis the poor man has in the past, *mirabile dictu*, often been better off than his rich neighbour who has had the help of a restlessly resourceful laryngologist. With regard to modern methods of diagnosis, the authors devote much space to the opsonic index, von Pirquet's reaction falling into the background.

As for treatment, this book is a useful milestone, showing the progress made in recent years. Readers will perhaps come to the conclusion that this "progress" is chiefly to be noted in the discarding and discrediting of such remedies as tuberculin which have diverted research from more promising themes. A new chapter on artificial pneumothorax marks the authors' adherence to this treatment which they recommend in a limited number of cases.

DISEASES OF CHILDREN.

Eleventh edition. By the late Sir James Frederick Goodhart, Bart., M.D., LL.D. Aberd., F.R.C.P. Edited by George Frederick Still, M.A., M.D., F.R.C.P. London: J. and A. Churchill. 1921. With 60 illustrations. Pp. 942. 32s.

A new edition of this tried and trusted volume appears under altered circumstances, for owing to Sir James Goodhart's death the responsibility and labour falls to Dr. Still alone. With a book which has been before the profession for 36 years, and which is, with justice, regarded as a standard work on the subject with which it deals, there is little room for comment or criticism. We must be content to examine the attitude which it takes towards recent advances in the knowledge of pediatrics, and to estimate to what extent it conforms to modern teaching. In regard to the latter inquiry it may be said at once that the new edition is a presentment of all that is sanest and best in English thought and practice in the study of children's diseases. We note, in passing, that no attempt is made to meet the continental conception of infant feeding and of the dyspeptic disorders of children, which has been planted out so widely in the United States, and has obtained a footing in this country. No place is found for separate descriptions of fat-dyspepsia, carbohydrate-dyspepsia, protein-dyspepsia, starch-injuries, and the other various articles of belief of this school. So often is the science of the laboratory distorted to meet the varying needs of clinical medicine, that we thank Dr. Still for his timely words on the application of caloric estimations to infant feeding. "As a guide," he says, "to the general utility of a food its caloric yield has a very limited value. Still less is any such rule-of-thumb method reliable in dealing with the individual infant, for it ignores idiosyncrasy altogether, and, as we all know, one infant can utilise more of one constituent, another of some other, in the food."

Blood diseases are dealt with somewhat briefly; we note that splenic anæmia is taken as synonymous with pseudo-leukæmia, and that no mention is made of the adult form. Nowhere does splenectomy appear to be mentioned, though it has been strongly advocated for splenic anæmia both of the adult and pseudo-leukæmic forms and for familial acholuric jaundice, and many recoveries have attended it. The modern views that the acute leukæmia of children is essentially myeloid in character, in contradistinction to the usually accepted theory of lymphatic origin, and that the cells seen in preponderance in the blood are not lymphocytes but marrow cells, pass unnoticed. Posterior basic meningitis is still kept apart from cerebro-spinal fever; we think that most observers would now regard it as cerebro-spinal fever in infants, occurring in sporadic form. Official circulars would have us believe that rickets has definitely been placed among the group of deficiency diseases. In this regard it is interesting to find that Dr. Still does not accept the vitamine-deficiency explanation as proven, though he sees much to recommend it.

The book occupies a place almost alone in this country in the literature of children's diseases. The editor's hope "that this edition, like its predecessors, may mark a fresh advance in usefulness and interest" is amply fulfilled.

PHARMACOLOGY, TOXICOLOGY, AND MATERIA MEDICA.

1. *A Text-book of Pharmacology and Medical Treatment for Nurses.* By J. M. FORTESCUE-BRICKDALE, M.A., M.D. Oxon., M.R.C.P. Lond., Captain, R.A.M.C. (T.F.). London: Henry Frowde and Hodder and Stoughton. 1920. Pp. 392. 25*s.*
2. *Poisons: Their Effects and Detection.* Fifth edition. By ALEXANDER WYNTER BLYTH, M.R.C.S., F.I.C., F.C.S., &c., and MEREDITH WYNTER BLYTH, B.A. Cantab., B.Sc. Lond., F.I.C., F.C.S., &c. London: Charles Griffin and Co. 1920. Pp. 745. 36*s.*
3. *Scientific and Applied Pharmacognosy.* Second edition. By HENRY KRAEMER, Ph.B. (Chemistry), Ph.M. (Pharmacy), Ph.D. (Botany). New York: John Wiley and Sons; London: Chapman and Hall. 1920. Pp. 741. 38*s.*

1. AMONG recent additions to that excellent series, the Oxford Medical Publications, is "A Text-book of Pharmacology and Medical Treatment for Nurses," by Dr. J. M. Fortescue-Brickdale. The purpose of this book is to explain the principles of medical treatment to nurses, on the assumption that the more fully the ideas underlying directions given by medical men are appreciated, the more accurately and intelligently is the work done. At the same time an effort has been made to impress nurses with the difficulties surrounding practical therapeutics, which can only be met by a training and experience differing widely from their own. The author has carried out this plan with marked success, especially in the first or pharmacological section of the book. The pharmacology of all the more important drugs is dealt with in a clear and straightforward manner, simple explanations of chemical and physical theories being given where necessary. We would suggest, however, that in another edition the number of rarely used synthetic drugs might be reduced with advantage; it must be remembered that, compared with a medical student, the average nurse has but a limited amount of time and energy available for reading during her course of training. This portion of the book concludes with a good section on sera and vaccines.

In the second section the usual treatment of the common diseases—and of some not common—is described, but clinical and pathological descriptions are not given, nor is dosage dealt with except in connexion with the treatment of poisoning. We think that it would have been preferable to lay rather more stress upon general principles and less upon those details in regard to which there is divergence of opinion among physicians. On the other hand, one would have expected to find in such a text-book somewhat fuller descriptions of the technique of treatment usually entrusted to nurses; we have noticed no mention of nasal feeding, for example, and in the directions for giving hot-air baths in the treatment of nephritis there is no indication of the temperature required. Appendices contain useful information on disinfection, the treatment of cases of poisoning, and other matters. The book is lucidly written, and is provided with excellent illustrations, including a number of coloured figures of medicinal plants. A nurse by mastering the contents of this volume will certainly render herself considerably more efficient as an assistant to the physician.

2. We are pleased to note the appearance of the fifth edition of Wynter Blyth's "Poisons, their Effects and Detection," which has ranked for years as a standard work on the subject. In view of the importance of methods for identifying minute quantities of poisonous substances, the authors have laid stress in this edition on microchemical and physical aids to recognition, the latter having the advantage of not changing or wasting the material. Thus, among the new sections we see one on micro-crystallography, which deals with the determination of the angles of crystals, their refractive indices, and so forth, and scattered through the book there are many applications of these principles. The organic derivatives of arsenic and antimony, and the newer potent synthetic drugs generally, have received attention, as has recent progress in connexion with the constituents of poisonous plants. Of such work, carried out since the appearance of the last edition, none rivals the brilliant exposition of the chemistry of ergot by Barger and his co-workers. Some account is given of recent investigations bearing on the variation of pharmacological action with chemical composition in certain groups of substances such as the atropine series, emetine and its derivatives, and the amines related to the active constituents of ergot; but such statements only serve to show how isolated, as yet, are the instances in which it is possible to identify any definite physiological effect with a certain chemical grouping. The number of deaths caused by each of the important poisons in England and Wales during the five years ending December, 1916, is given. Food-poisoning cases head the list, and of the remainder it is instructive to note the high place taken by certain poisons, such as hydrochloric acid (third on the list), the regulations governing the sale of which are the least stringent. Hydrochloric acid, it may be added, is not among the poisons which are obtainable only from qualified chemists; any dealer can sell it. A feature of this work is the account given of criminal and other poisoning cases. We were surprised, therefore, to see no mention of the Crippen case.

The subject-matter of the book as a whole has been brought well up to date, but the sections on ptomaines and food poisoning seem to have hardly received their share of revision. The bases formed during putrefaction are fully described and there is no indication how slight is the evidence upon which they have been regarded as causing poisoning when taken by the mouth. The Gaertner group of organisms, whose toxins are now generally held to be the cause of the majority of cases of food poisoning, deserve more than the few lines devoted to them. No reference is made to the use of poisonous gases in warfare. It is true that comparatively little has been made public on this subject at present, but the investigation of such substances and their effects must have brought to light facts of great toxicological interest. We hope that it will be found possible to add to the information already liberated, without forgetting the advice quoted by Lord Fisher shortly before his death: "Give not the things that are profitable to thee to a strange nation."

3. The first edition of Professor Kraemer's "Scientific and Applied Pharmacognosy," a book dealing systematically with all the more important crude vegetable and animal drugs, their constituents, adulterants, and so

forth, appeared in 1915, and we now welcome its successor. Although a considerable amount of new matter has been added, notably in connexion with progress in pharmaco-chemistry and drug cultivation, the volume has been rendered less bulky and more convenient to handle. Here also we find the importance of physical and micro-chemical method emphasised, these being the departments of analytical work in which the most important advances have been made of recent years—at least as far as the examination of foods and drugs is concerned. Few commodities demand such progressive methods of analytical control as these, on account of the chemical complexity of the substances to be dealt with, the frequency of their adulteration and sophistication, and the scientific methods now employed in preparation for the market. Speaking, presumably, of America, the author says that during the past 10 years something like 50 per cent. of the powdered drugs on sale were adulterated and the trade in spices was even worse; we cannot believe that conditions have been quite as bad in this country, but there is room for improvement. Lately more stringent legislative and analytical control has brought about a great change for the better. Among recent applications of physics we may mention an extended use of refractometric and polarimetric methods. The refractometer is not only useful in controlling the quality of oils and other products, but has been the means of indicating the presence of hitherto undetected constituents, as in the case of eucalyptus oil. The micro-polariscope is being more extensively used for the identification of alkaloids, and a process for the determination of morphia by the polarimeter has recently been described. X rays may be used to detect mineral impurities in such drugs as asafœtida, and the electrolytic determination of metals is continually finding fresh applications.

The author rightly lays stress upon the importance of crystallography as part of the scientific equipment of the pharmacognosist. In this country, at any rate, the acquaintance of analytical chemists with this subject is not always very close, and this remark applies to pharmacists with even greater force. Space can hardly be found for it in the curriculum of the latter under present conditions, but possibly a curtailment of the study of the many little-used drugs, to which pharmaceutical students are now required to devote their attention, might solve the problem. Professor Kraemer has met with considerable success in using the characters of the crystalline sublimates obtained by heating various drugs as aids to recognition, and in the identification of crystals he finds their behaviour on the thermostage of a microscope very useful.

The book is intended for the use of students in pharmacy, as a handbook for pharmacists, and as a reference book for food and drug analysts and pharmacologists. As far as it is possible to supply these needs within the limits of a single volume, it fulfils its purpose admirably. Although for pharmaceutical students it is somewhat overloaded with detail, as a work of reference it is excellent. Analysts will find the illustrations of microscopical details particularly useful in identifying drugs and determining the purity of powders.

ANATOMY OF THE HUMAN SKELETON.

Second edition. By J. ERNEST FRAZER, F.R.C.S. Eng., Professor of Anatomy in the University of London. London: J. and A. Churchill. 1920. Pp. 284. 36*s.*

THE author has not done himself justice in choosing a title for his book, the scope of which is far larger than it suggests. Instead of drily describing the dry bone carefully cleaned and separated from neighbouring structures, Professor Frazer has sought to portray the bones as they are found in the human body with the various structures in relationship to them, and to explain the effects of these relationships on the structure and conformation of the bone. To this end the author gives 219 illustrations, many of them coloured, done by his own pen and brush. Naturally many details are given which are lacking from other text-books, for they can only be seen by the receptive eye of the anatomist himself. *It is just this feature of the book, the appreciation of anatomy for its own sake and not as a means to an end, that is characteristic and of value.* In the present edition the description of the illustrations is written beneath and not on the opposite page, as in the previous edition—an improvement, thereby saving the reader much needless turning backwards and forwards. The small errors which we noted in the earlier edition have now been rectified. We can confidently recommend this book to all students of anatomy, and more especially to those who are candidates for the higher examinations in this subject. Just as in the last generation the work of George Humphry was the chief agent in giving medical students a living interest in the bony skeleton, this book of Professor Frazer's has already been the means of transforming what is too often a permanent distaste for anatomy in the present-day student into a positive enthusiasm.

THE POCKET ANATOMY.

Eighth edition. By C. H. FAGGE, M.B., M.S. Lond., F.R.C.S. London: Baillière, Tindall, and Cox. 1920. Pp. 313. 5*s.*

IT is not necessary to enter into detail in dealing with this little book; the fact that it has reached its eighth edition and fiftieth thousand is in itself enough to show that it serves its purpose well. The old nomenclature has been reinstated throughout. It is undoubtedly the best of the books which serve for refreshing the mind of the student and recalling the academic points of his study.

OLD AT FORTY OR YOUNG AT SIXTY.

By ROBERT S. CARROLL, M.D. New York: The Macmillan Company. 1920. Pp. 148. 13*s.*

THERE have been many books written on the subject of old age, how to procure it and how to enjoy it, from the time of Cicero's "De Senectute" down to Sir Hermann Weber's "Means for the Prolongation of Life," and we doubt the need for yet another book on the subject. However, Dr. Carroll has set down in the work now before us a number of somewhat obvious aphorisms and principles of which those who have reached their fortieth year should take cognisance. Practically they may be summed up in the old lines from the De Regimine Sanitatis of Salerno—

> Si tibi deficiant medici, medici tibi fiant,
> hæc tria, mens hilaris, requies, moderata diæta.

Dr. Carroll rightly lays stress upon the necessity for work in moderation as tending towards a happy frame of mind, and of exercise, also in moderation. "Be cheerful; sleep well, and do not eat too much," sounds easy, but all books on old age and how to enjoy it seem to ignore the fact that, if not riches, at least a competence is necessary. The present unrest all over the world is in great part due, we fancy, to the ever-present spectre of a joyless old age, without the ability to work, and therefore with the accompanying conditions of want. But given even a very small income, old age should be a time of rest and of looking forward to the next life with calmness and that attitude of mind so beautifully described by our own poet Waller in his stanza which begins "The seas are quiet when the winds give o'er."

A *NURSE'S HANDBOOK OF OBSTETRICS.*

For Use in Training-Schools. By JOSEPH BROWN COOKE, M.D., Fellow of the New York Obstetrical Society. Ninth edition, revised and enlarged. By CAROLYN E. GRAY, R.N., Superintendent of City Hospital School of Nursing, Blackwells Island, New York City; and PHILIP F. WILLIAMS, M.D., Instructor in Obstetrics, School of Medicine, University of Pennsylvania. London and Philadelphia: J. B. Lippincott Company. 1920. Pp. 468. 12*s.* 6*d.*

LITTLE need be said in praise of a book which has proved its worth by running through nine editions since it first appeared in 1903. The present edition has been extensively revised and enlarged, and the more important advances in practical nursing incorporated.

New illustrations and some coloured plates have been added and a section on prenatal nursing. The advantages which result from this branch of nursing is demonstrated by the statistics of the Committee for the Reduction of Infant Mortality of the New York Milk Commission. These figures show that among 3000 women who had close supervision during their pregnancy there was a 69 per cent. decrease in the maternal mortality, a 28 per cent. decrease in the deaths of infants under one month, and a 22 per cent. decrease in stillbirths. The importance of such preventive treatment is evident when we remember that over 15,000 women die annually in the United States from childbirth. This book is an extremely good one, and this edition fully maintains the high standard of the previous ones.

JOURNALS.

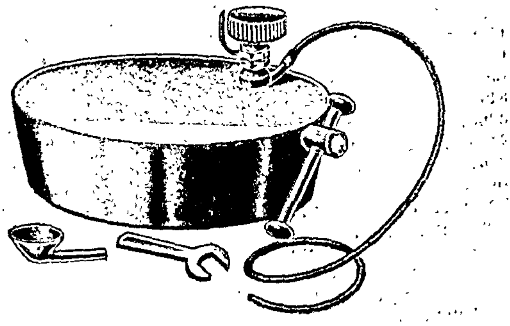
Journal of the Royal Naval Medical Service.—In the issue for January a paper by Surgeon-Commander L. F. Cope, R.N., gives account of his experiences on special service in the Danube from May to September, 1919. It will be remembered[1] that this officer had overcome an epidemic of typhus in Belgrade in December, 1918. In this present period he had little medical work to do, but his account of the fertile Hungarian plain, of the disorganisation and poverty due to Bolshevism, locally held to be entirely engineered by Jews, and his esteem for and confidence in the future of the Hungarians are all interesting, as is also his account of his work on the Food Mission, which existed to buy food but had no currency the peasants would accept. Like others, he tells of the work achieved by individual *British officers in apparently hopeless situations.* His monitor was visited at Budapest by the commandant of the Bolshevik Marine Guard, himself formerly a sailor in the Austrian Navy, in which his present secretary had been a lieutenant. But this topsy-turveydom did not help military action, for the Bolshevists were inattentive and always late, so the threatened monitors got away unharmed; Captain V. H. Haggard, R.N., too, by his mere personality, rescued from them two motor-launches they had seized.—Surgeon Rear-Admiral P. W. Bassett-Smith publishes a very interesting report by Surgeon-Commander W. R. Harrison on Autogenous Pyorrhœa Vaccine made at Greenwich for individual patients of the Dover Patrol. Generally a short Gram-positive streptococcus was isolated. The dental surgeon reported that the loose teeth of each case should be removed, but under local treatment, scaling, hydrogen peroxide or other mouth wash, and vaccine, "the teeth have become *firm, pus has stopped, and gums have healed and hardened.* These are cases which formerly would have had their mouths stripped of teeth." This all means a great advantage to the individual, and a large saving of service to the Navy, and further credit to vaccine therapy.—Surgeon-Commander H. C. Whiteside, who will be remembered for his work on Malta fever 15 years ago, has an article on the Bacteriology of Cerebro-spinal Fever. It is noted that few cases occurred during the war in sea-going ships, 8·7 per cent. only in 1914 and 1915, 13 per cent. in 1916, 1917, 1918, which is tentatively ascribed to the higher degree of immunity of the trained man over the recruit living in new conditions, while fresh air and sunshine cure the carrier condition far better than local treatment. The carrier is thought to be hardly a danger to himself, as so few cases occurred in their isolation camps.—Surgeon-Commander H. S. Burniston (who is Fleet Medical Officer of the Atlantic Fleet, of H.M.S. *Queen Elizabeth*) and others are anxious that a standard treatment for syphilis (also for gonorrhœa) shall be promulgated by authority; in accordance with that all cases would be treated. Then the men will not be confused by the varying opinion of successive medical officers, but having only one system, the best, put before them, they will easily be guided to accept that. Instructions such as asked for appear to have been issued for the treatment of soft chancre. Ablution cabinets are in future to be constructed adjacent to sick bays, and specialists in genito-urinary and venereal diseases are being appointed to fleets, though it is discussed whether all medical officers should not be trained themselves skilfully to administer all such treatments.—We all know the old aphorism about the swing of the pendulum, and are reminded of it in reading Surgeon-Captain M. L. B. Rodd's first note. Things forgotten come back again, but come back with a difference. In the old days "strapping" was applied to ulcers, across them, to draw the edges together and accelerate healing. This method was discredited by surgeons trained in antiseptic surgery and disused. Now Surgeon-Captain Rodd, following Beck of Chicago, recommends that granulating wounds, if healing but slowly, shall have strips of zinc-oxide plaster applied (but note the difference), not across but along the edges of the *granulating* wound; the plaster seems to act as a support to the delicate, rapidly ingrowing epithelial cells. Surgeon-Captain Rodd reports also an operation for strangulated hernia with an acute appendicitis in the sac, and a case of a recurrent torsion of the spermatic cord; also he successfully removed a spleen, ruptured by a punch in the left loin. Very careful provision is being made in the Navy for thorough dental treatment for officers and men, and dental history cards for all are instituted.

New Inventions.

A WARM ETHER BOMB.

THE advantages of administering warm ether are now generally recognised as the result of experimental and clinical observations by Gwathmey, Pembrey, and Shipway. These advantages may be briefly summarised as follows: Diminished loss of body heat; diminution of shock; diminished buccal and bronchial secretions; it is less toxic in its effects on the tissues; warm ether is less irritating to breathe in the conscious stage, and less likely to cause respiratory spasm—in consequence, induction is more rapid; after-vomiting is lessened; there is diminished risk of lung complications.

The apparatus here illustrated, whilst delivering warm ether vapour, has other advantages likely to be of value. 1. The ether is self-delivering and no bellows are required. 2. It is simple, and portable in a small handbag. 3. There is nothing to break. 4. The delivery of the vapour can be very accurately controlled by means of a needle-valve. 5. It is possible to get a stronger vapour than by other methods. 6. It is adaptable to any ordinary open mask, and easily attachable to any closed nitrous oxide or ether inhaler. 7. It affords a convenient means of anæsthetising animals with ether if fitted either to a mask or animal box.



The apparatus consists of a strong steel vessel, capable of holding half a pint of ether and tested to withstand a pressure of 250 lb. per square inch. It is fitted with an aperture for filling, which is closed with a screw plug, and with a needle-valve to regulate the supply of vapour. The valve has a graduated ebonite top and a pointer which indicates when the valve is closed, or the extent to which it is open. The delivery pipe of the valve is connected by rubber tubing of small bore to an ordinary open ether mask by means of a small metal tube, inserted through the covering of the mask. The temperature beneath the mask is between 90° and 98° F.

The apparatus has been in use for 3½ years and has proved perfectly satisfactory, but difficulties in manufacture arose during the war. These have now been overcome and the apparatus is procurable from the Condensed Gas Company, 59-63, Grosvenor-street, All Saints, Manchester.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 12, 1921.

Following-Up.

PROGRESS in clinical medicine and surgery is to a large extent retarded by the absence of definite evidence of the late results of treatment. If such evidence could be obtained there is no doubt that much of the difference of opinion regarding various lines of treatment would be overcome. It has long been felt that there is a tendency for surgeons and physicians to continue using methods of treatment which were in vogue when they were first appointed to a hospital staff, and which have since become obsolete. One or two good results in the past led to the impression that the treatment is satisfactory; whereas, if a whole series of cases had been investigated a different conclusion might have been reached. To place the various lines of treatment, and especially surgical treatment, upon an accurate basis it is essential to have some form of a "follow-through" department, whereby the cases can be traced for months or years after the treatment is instituted. Several such departments have been started in America, and in London those at the London Hospital are now well established.

Dr. C. L. GIBSON has published an analysis[1] of such a department in the New York Hospital which emphasises the value of this work. The method there followed appears, however, to be incomplete; but, as the author states, it is at present upon trial, and unquestionably will be modified and improved in course of time. For such a department to be of real value every case must be followed whether ill or well, no case must be discharged without the needful information to secure following-up, and means must be taken of determining the number of deaths which occur. By this means the results can be accurately determined over a period of many years. Apparently at the New York Hospital patients are told to come up in three months time, and to report at any time if not so well. The failure of patients to follow such instructions is well known, and apparently this still occurs in the hospital mentioned, for the statement is made that the results appear to be bad owing to the fact that a large number of patients remaining in good health, and having no complaints, do not respond to the request for investigation or examination. These difficulties are well recognised at the London Hospital, where every patient on his discharge from the ward is given a dated card for his next examination, which is usually held two to three weeks later. Three days before this date becomes due a postcard is sent to remind him. When he appears notes of progress are made on the same sheets used while he was an in-patient, so that there is no discontinuity between the in- and out-patient notes, and should he relapse and be admitted again further in-patient notes are added to the same sheets. There is thus on one bound set of sheets a complete history of the patient's hospital life. At the end of the examination he is given a date for his next visit which is entered into a book by a secretary, who sits with the surgeon, and again three days before this examination is due he is written to. Cases progressing satisfactorily may be given a date 6 or 12 months ahead. If simply told to come again in that period probably 50 per cent. would fail to appear, but when reminded with a card two or three days before the date is due it is found that only 2 per cent. of them fail to attend. By such means very accurate data of the value of operative procedures at present under dispute are obtained and by keeping separate card indexes of diseases and operative measures the notes can be readily referred to in a few minutes and the results investigated at short intervals. The relative values of disputed lines of treatment is, in this way, shown by the results of gastro-enterostomy for pyloric and lesser curve ulcers of the stomach, by the effects of partial thyroidectomy for exophthalmic goitre, and by the results of the various forms of therapy for carcinoma of the colon. The patients appreciate the department, which at the London Hospital is held, not in the out-patient department, but in a room lent by the hospital committee, so that there is a personal relationship between the surgeon and his patients, who thus feel that they have what must be regarded as a health insurance. Should they not be making satisfactory progress they can come up on the appointed day of any week, whether written to or not, and if a new disease has arisen which requires treatment in another department they are then referred to that department without loss of time. The value of continuous record is recognised by these patients to the full.

The analysis of Dr. GIBSON, although admittedly only a preliminary report, already brings forward many points of considerable interest, and, as the author states, some of the results are much better and others much worse than were expected. But he indicates clearly that if the method of following-up were more generally followed the majority of surgeons would be considerably less satisfied with some of their methods of treatment—a matter of profound public importance. The article is of value as laying stress upon the importance of a department which should have a great influence upon future treatment. There can be no doubt that it is only by such records of past history and happenings that real progress can be made in medical or surgical treatment, and it is to be hoped that establishments of this sort will rapidly be founded in all big hospitals.

Voluntary Hospital Policy.

THE opening statement of the policy of King Edward's Hospital Fund, as passed by the General Council of the Fund on Jan. 26th, should be carefully weighed. It lays down as the conclusion arrived at by those who framed it "that the voluntary system of hospital management and control should be preserved as being the most efficient method of providing at the least cost the best medical and surgical treatment, combined with advance in medical knowledge and practice." Unless the accuracy of this estimate can be impugned by expert opinion at any rate comparable with that at the command of King Edward's Fund, the voluntary system as the one which can supply the greatest efficiency at the least cost should appeal to the Government and win the support of the country.

---

[1] Gibson, C. L., "An Analysis of the Results of Six Years' Follow-up System in a Hospital Surgical Service," Annals of Surgery, December, 1919, p. 661.

The situation requires not only the earnest attention of the Government, but immediate consideration and a definite early pronouncement of the policy that will be followed. Uncertainty as to when and on what conditions the State will finally intervene can only lead to decrease of subscriptions with an accompanying prospect of a larger demand upon public revenues at some not distant date. This uncertainty as to the future position of hospitals is already contributing to the diminution of their incomes, in combination with the certainty that their position of dependence exclusively on the charity of the benevolent cannot be maintained. The question of their future at its present stage is one which the Government, and the Government only, can decide, for there is no way of ascertaining the views of the public as in the case of civil politics. The range of classes and interests from whom opinions would have to be obtained is too wide, including the wealthy, or comparatively wealthy, with those who under the proposals of the Council of King Edward's Hospital Fund may be asked to contribute to the expenses of their own treatment, and those others for whom the help which the hospital affords will always be the gift of charity. Later, when the course adopted has developed, its practical success or failure should be established beyond doubt. If the contributions to be raised voluntarily fall below the proportion necessary to maintain the voluntary status at a prescribed standard, the public vote will have been given, perhaps unconsciously, against the maintenance of the voluntary policy. In that event the taxpayer or ratepayer will be called upon to bear in that very different capacity the burden which he has hitherto been asked to shoulder as a willing and charitable friend of the people. Should the voluntary subscribers make this decision there will follow the opportunity for all to judge whether the Council of King Edward's Hospital Fund was right in recommending the voluntary system as producing the best results at the least cost. Whatever opinion may then be formed the final decision will have been taken. But there will be no possibility of reverting to the voluntary system when once it has been abandoned —an anxious thought for those of us who believe, with the Council of King Edward's Fund, in the paramount merits of the system.

Deep Radiotherapy.

There are signs of a widening interest in what is known as deep radiotherapy, but technical difficulties attend the irradiation of the deeper structures of the body. Recent discussions at the Sections of Electrotherapeutics and of Obstetrics and Gynæcology of the Royal Society of Medicine have shown considerable dissatisfaction among radiologists, not so much with the sources of radiation at their command as with the methods in use for measuring the dose admininistered. There is at present no way of measuring the dose of radiation absorbed by a tumour situated at a depth in the body; we say absorbed advisedly, for only those rays which are absorbed can produce chemical and physical changes, and it is only the amount of radiation that is absorbed by the irradiated tissues which should be included in the term dose. In this connexion some misconception has arisen as to the virtue of very penetrating X rays; it has even been said that in the case of very penetrating rays the amount absorbed by the tumour cells is negligible. As a matter of fact the amount absorbed may be quite large. A beam of X rays issuing from a bulb, at an alternative spark gap of 10 inches, consists of a mixture of rays, generally spoken of as soft, medium, and hard, the hard type predominating with this gap; we will assume that some measure of the intensity of this composite beam can be made photographically. A sheet of aluminium 10 mm. thick, interposed in the path of the beam, has the effect of weeding out all but the hard rays; the beam passing through such a filter is practically homogeneous, but its intensity would, on measurement, be found to be reduced to about one-fifteenth of its original value. If we use for our intensity meter a strip of photographic paper, it is only the small fraction of radiation absorbed by the paper which determines the tint. Prolong the exposure in the second case 15 times, and the resulting tint will be the same as before; we have made the film absorb the necessary amount of the penetrating X rays to give the same result. Hence, in dealing with very penetrating X rays or the still more penetrating gamma rays of radium, the difficulties of getting the requisite dose into a deep-seated tumour do not arise from the degree of penetrating power; they arise first from the limited tolerance of the human skin to these rays, and secondly, from the diminishing intensity of the rays as the distance from their source increases.

Over-dosage of the skin is avoided by employing multiple ports of entry, the rays converging from various directions upon a deep-seated tumour. A gradual fall in intensity through the tissues takes place, however, not only because of the increase in distance from the source but also because of the absorption of the beam by each successive layer; and this variation will be minimal when the penetrating power is maximal. By using a very hard X ray bulb (say 12 inches spark-gap) at a distance of 30 cm. from the skin of the patient, and filtering the rays through 10 mm. of aluminium, the ratio of intensities at 1 and 10 cm. depth in the tissues would be about as 100 : 30. This may indicate to some extent how difficult it is to obtain uniformity of radiation throughout a tumour mass; and if no real uniformity exists we may well ask what is meant by the term "dose of X rays administered." An analogy would be the oral administration of a dose of strychnine; a rather difficult physiological inquiry would be needed to determine how much reaches a certain organ. We have not even arrived at this stage in our radiation measurements. Though it is true that by placing an intensity meter in the path of the beam we may say what intensity of radiation is incident upon the surface of the patient, this is not a measure of the dose; the most that can be done at present is to specify fairly accurately the way in which this intensity falls off as the beam makes its way through the tissues, and pictorial charts of this kind might prove very useful to radiologists. But this is far from being a measure of the dose of radiation. Our electroscopes or photographic films can only act as *intensity* meters. They do not measure the *energy* of the beam of X rays; to do this they would have to absorb it completely. When modes of measurements of this kind are adopted, the time will have come to establish a unit of X ray energy, a demand that has been met in other parts of the spectrum—for example, light and heat. Contrary to the popular conception, it is a simpler matter to give a deep-seated tumour uniform irradiation with highly penetrating rays than with lightly screened X rays consisting of soft, medium, and hard constituents. The next matter for consideration is whether these soft, medium, and hard X rays have appreciably different effects upon actively growing tumour cells in all cases, if the dose absorbed is the same; in other words, have these different rays a differential action? On the answer to this question will depend very largely the warrant for an extended use of the more highly penetrating X rays. We cannot be too careful in adjudging the evidence on this point. If the evidence is brought from a radiological clinic, the first criticism almost invariably directed upon it is that it is practically impossible to arrange under clinical conditions that the cells of tumours in different cases have received the same dose. A rigorous proof of the fact that, in equal doses, "soft," "medium," and "hard" X rays have similar destructive effects upon tumour growth, can perhaps hardly be expected from the clinic itself. A greater degree of exactness is possible in examining this question as far as it applies in animal tumours; and although the evidence is limited, it points to the fact that if the tumour cells are made to absorb equal quantities of soft and of hard X rays, the quantity required for a lethal dose to the cells is not appreciably different in the two cases.

It is in such problems as deep radio-therapy that we are made to realise the necessity of laboratory investigations. Up to a certain point it looks as though the reaction of any particular type of cell is a function of the amount of energy which it absorbs and converts into some other kind: as it is submitted to radiation where the wave-length is inappropriate for this conversion of energy, there is a cessation of reaction, when we say that electro-magnetic radiations have a differential effect upon one and the same variety of cell. Otherwise, if we concentrate our attention upon one variety of ray—say some X ray beam about the middle of the three octaves made use of by the radiologist—by acting with the same beam upon a large variety of tissues, the beautiful phenomena of selective action are disclosed. In the region of the spectrum where X rays have their place, the absorption which the rays suffer in passing through different materials is intimately bound up with the nature of the atoms forming the material, and not with the molecular structure which is so important in the problems of light absorption and transmission. Atoms of high atomic weight absorb a beam of X rays more readily than the atoms of low atomic weight, with exceptions dependent upon characteristic X ray phenomena. If we restrict our attention to one type of absorbing substance, say aluminium or water (about equal in absorbing power to the soft tissues of the body), then it is found that the X rays of long wave-lengths—i.e., soft X rays—are much more absorbed than those of short wave-lengths. This of course accounts for the filtering effect of a sheet of aluminium, its tendency being to stop the long waves and to let through the short ones; some of the short ones are absorbed too, but a much smaller percentage. An X ray which had twice the wave-length of another would be absorbed nearly six times as much by a sheet of aluminium. Numerical values of the average wave-length of a beam of X rays can be found by absorption measurements, and when these come to be used by radiologists instead of the terms "soft" and "hard," a valuable aid to exactness will result. As to the antagonistic effects of different rays, Professor PECH has described some experiments,[1] which appear to show that radiation from one part of the spectrum (visible) acted in an antagonistic manner to the rays from another part (ultra-violet). We look with interest to the development of such investigations in view of their significance in radio-therapy.

Annotations.

"Ne quid nimis."

"SPECIAL" INTERNAL EXAMINATIONS IN MEDICINE.

THE dissatisfaction felt by all teachers with the examination system is as chronic as a winter cough, and as incurable. The fact that the malady increases with the age and individual distinction of the teacher makes it no easier to treat. Occasionally it lights up in acute form, and the result is a series of indeterminate conferences, culminating in a discussion such as that held on Feb. 7th at a meeting convened by the Dean of the Faculty of Medicine in the University of London. The controversial point was a proposal to institute "special"[2] internal second examinations for medical degrees, arising out of a request from University College for permission to hold such examinations in organic chemistry in March, 1921, and in anatomy, pharmacology, and physiology in July, 1921, and similarly in March and July in future years. The Academic Council have had this request under consideration for some time, and a conference was called in February, 1920, of medical representatives of the Senate and of schools and colleges of the University to discuss the expediency of granting this permission. At the conference Professor Starling was the chief advocate for the innovation. He argued that though the present system of examination was perfectly fair, it was one which absolutely destroyed originality of teaching. He held that cast-iron uniformity was not wanted, that in each school there ought to be a tone of individuality, and that it was a way of thought rather than facts that a man should acquire. Against this it might be said, and indeed was said in effect by the opponents of the proposal, that for the practice of medicine more is wanted than education in certain principles. There is, indeed, no scope for originality of teaching in the crowded medical curriculum, unless it be selective; and may this safely be allowed? No analogy can be drawn between medicine and the other faculties in this matter. It may be, and probably is, more conducive to an appreciation of English poetry to know thoroughly the period of Chaucer or Milton than to survey the whole field of English literature through the unilluminating pages of a matriculation cram-book. But the extensive medical syllabus laid down under the supervision of the General Medical Council has been framed to include only that ground which it is deemed essential for a qualified doctor to have covered, and independent examiners are surely the best judges as to whether he has covered it. No arguments throwing fresh light on the question appear to have been brought forward at the meeting of the Faculty, where after much discussion it was ultimately and, we think, wisely decided that the institution of "special" internal examinations in the Faculty was inadvisable.

---

[1] Comptes Rendus de l'Acad. des Sciences, May, 1920.

[2] A "special" internal examination is one peculiar to the particular school where it is held. It is conducted by the teachers at the school with the association of an external examiner or examiners, and is designed to enable the students to be examined on the particular course that they have been taught.

The University of London has under its constitution a hard struggle to maintain cohesion, and if internal examinations conducted in its name are not uniform there would seem no need for its continuance as a corporate body. The examination system should be attacked boldly and as a whole by our educational authorities, but we think that experiments might well be conducted where the struggle for life between constituent colleges and between external and internal students does not complicate a problem in itself sufficiently intricate.

THE TREATMENT OF GASTRIC AND DUODENAL ULCERS.

IN spite of the large amount of work which has been carried out in recent years, in investigating the causation of gastric and duodenal ulcers, the problem remains unsolved, especially in regard to the conditions preceding ulceration and those leading to the chronic forms. Experimentally, acute gastric ulcers similar in character to those occurring in man have been produced in animals by Dr. Charles Bolton, but these tended to heal rapidly, unless meat was given or unless some degree of pyloric stenosis was artificially induced. There is now evidence in man that under appropriate treatment, notably rest and careful diet, acute gastric ulcers may heal satisfactorily, and the same is almost certainly true of duodenal ulcers. It is in regard to the chronic ulcers that the choice of treatment is at present so difficult, and concerning this choice the most widely different opinions are held. This is well illustrated in the discussion on this subject before the Royal Glasgow Medico-Chirurgical Society, published in THE LANCET of Jan. 22nd (p. 172). It was a happy arrangement by which the discussion was opened by a physician, a surgeon, and a general practitioner, as it is important to establish the rôle of each in the treatment of these conditions. Whereas formerly treatment was almost exclusively medical, except in the case of perforating ulcers, the pendulum has swung so that in the minds of many practitioners and surgeons the bias is towards surgical treatment in the majority of cases. The immediate results of surgery in many examples of chronic ulcer where medical treatment has failed are so dramatic that there is some excuse for this surgical bias. It should, however, be remembered that surgery also fails in some cases, and that the subsequent development of jejunal ulceration, the vicious circle, and the regurgitation of bile are often dire instances of this. Indeed, the varying technique and form of operation employed by different surgeons, and the not infrequent necessity for secondary or subsequent operations, indicate that the eclectic surgical procedure is yet to seek.

It is a truism that more can be learnt from a study of failures than of successes, and what is needed now is a critical collective study of the causes of failure of both medical and surgical forms of treatment. It is admitted that the surgeon often succeeds where medical treatment has failed, and it is claimed by some of the protagonists of medical treatment that, if medical measures were employed early enough and more efficiently, the surgeon's aid would rarely be necessary. Study of the results suggests that the cases in which surgery is most successful are those of the chronic ulcers, leading to cicatrisation with its sequels of delayed emptying, stasis and dilatation of the stomach. This is almost what might have been anticipated. The aid given by surgery is mechanical, and its chief success is in relieving the mechanical sequels of ulceration. The fundamental problem of the treatment of these ulcers is a more profound one and is essentially medical. The disturbances of vital function, whether secretory, nutritive, or muscular, which lead to ulceration, have to be prevented, and for this purpose further study of the symptoms in their early stages is desirable.

We published an interesting contribution to this aspect of the problem from Dr. E. P. Poulton last week. [illegible] is the results of his investigation of the cause and relief of pain in gastric ulcer. By means of special tubes passed into the stomach and duodenum he has studied the effects of varying intra-gastric pressure. He finds that an important element in the pain of gastric ulcer is distension of the stomach, and that it can be relieved by means of the gastric and duodenal tubes. His results are also of interest as confirming the views of Dr. A. F. Hurst in regard to visceral pain, which are the subject of correspondence in our columns this week. Dr. Poulton found that when distension of the stomach was induced by the introduction of air at a pressure of 20 cm. of water, an actual sensation of pain was produced in the cases where gastric ulcer was present, while a feeling of fullness was induced in other conditions. This reaction cannot, however, be used for purposes of diagnosis since he observed it in a case of carcinoma of the pancreas in which no gastric ulceration was found post mortem. He reports benefit in a considerable number of cases of gastric ulcer treated by the aid of the gastric tube in the manner he describes, but he is careful to point out that his work is still in the experimental stage, and that he is not prepared as yet to recommend it as a general mode of treatment. He suggests that increased intra-gastric pressure may be a factor in the genesis of gastric ulceration, and his example should lead to his hypothesis being examined by other workers. We may have here a sign-post, pointing to measures of value both in prevention and treatment. In the medical treatment of gastric ulcer the recognition of the earliest stages, correction of faulty regimen and diet, and systematic rather than symptomatic treatment are required. Dr. R. O. Adamson, speaking in the Glasgow discussion from the practitioner's standpoint, urged that prolonged after-treatment was an essential in the endeavour to prevent chronicity and mechanical deformities which follow in the train of chronic ulcer. It is evident that the physician and the practitioner are alive to the fundamentals of the problems of gastric and duodenal ulcer.

UNWELCOME DRUG RESTRICTIONS.

WE summarised in THE LANCET of Jan. 15th the draft regulations issued by the Home Office with a view to the carrying out of the Dangerous Drugs Act which became law last August. These regulations concern the manufacture, possession, sale, and distribution of opium, morphine, cocaine, ecgonine, diamorphine and their salts, as well as of any preparations containing not less than $\frac{1}{5}$ per cent. of morphine or $\frac{1}{10}$ per cent. of the other alkaloids. It is, we suppose, inevitable that those concerned with the legitimate use and distribution of these drugs must suffer some inconvenience from the restrictions designed to prevent their illegitimate use, but there should be a just and proper apportionment of inconvenience. After careful study of the regulations it is the concerted view of the medical, dental, veterinary, and pharmaceutical professions that the *restrictions are more than can be* borne. A Memorandum submitted last week by the British Medical Association to the Home Secretary states that the responsibilities and anxieties of medical practitioners are likely to be seriously increased by clerical restrictions *of a kind hitherto unknown* in medical practice; and the Council of the Pharmaceutical Society of Great Britain, in a lengthy manifesto, regards the objections to be so great as to demand an entire redrafting of the regulations. Nearly every regulation involves practical difficulties. From the medical practitioner's point of view it would be a hardship to insist upon the prescription being in writing when it might be typewritten or printed. Personal administration of a narcotic drug, say by hypodermic injection, without prescription appears to be vetoed, a limitation which looks impracticable in hospital work. What the Pharmaceutical Society quaintly calls the "four ledgers" regulation can hardly be fairly enforced on the practitioner who dispenses his own medicines; and the regulation requiring the percentage of any narcotic drug to be marked on the label of the bottle or package is calculated to defeat the intention of the Act itself, which was to prevent improper use of the drug, as doctors will no longer be able to conceal from patients the nature of the prescription One regulation apparently makes it impossible for a patient suffering from a sudden attack (say) of gall stone colic to obtain an emergency dose for the relief of pain, nor is it at all clear how such procedures as cocainising the eye, throat, or nose, or administering a morphine suppository, are to be carried out at all under the regulations The pharmacists naturally have grievances of their own, for while the Pharmaceutical Society has been pressing for the stricter allocation of the functions of prescribing and dispensing, the regulations prohibit pharmacists from retailing while permitting medical practitioners both to prescribe and dispense The fact that the dispensing of poisons is already safeguarded by statutory regulations under the Pharmacy Acts appears to have been ignored by the Home Office It is suggested that far too much importance has been attached to the value of mechanical forms and safeguards The essential part in any control is proper entry of the drugs as received on the one side and upon the other the use made of them, the outgoings being checked, qua sales by the poison book, and qua dispensing by the prescription book The British Dental Association is asking that the registered dentist should be authorised to be in possession of narcotic drugs so far as is necessary for the practice of his profession The Royal College of Veterinary Surgeons desires that its diplomates should be placed with respect to the treatment of diseased and injured animals on the same footing as doctors with respect to the use of drugs in human medicine All parties are uniting in the demand for further consultation with medical, dental, veterinary, and pharmaceutical representatives before the regulations are put in force The Home Office will do well to accede, inasmuch as upon the willing coöperation of the four professions largely depends the effective administration of the Act Ill considered restrictions have their dangers We have seen too much of successful evasion of narcotic Acts elsewhere to be content in this country with regulations which cannot be carried out both in the spirit and the letter

DILATATION OF UPPER PORTION OF INTERNAL SAPHENOUS VEIN SIMULATING FEMORAL HERNIA

Dr W E Sistrunk, of the Mayo Clinic, has recently called attention[1] to the possibility of mistaking dilatation of the upper portion of the internal saphenous for femoral hernia Trendelenburg has pointed out the frequency with which varicose veins are associated with incompetence of the valves guarding the orifice of the internal saphenous vein The valves mentioned are the first between the heart and the peripheral circulation of the lower limbs Their incompetence is probably a factor in producing dilatation of the vein This dilatation does not often produce a swelling likely to be confounded with femoral hernia, but Dr Sistrunk has seen one case in which mistakes were made by experienced clinicians Exploration of the femoral ring failed to reveal a hernia, and after operation the swelling developed again The practitioner who had originally examined the patient now diagnosed obturator hernia, and a second doctor diagnosed recurring femoral hernia The true condition was recognised by the surgical consultant, and a second operation corroborated his diagnosis The differential diagnosis is not difficult In both conditions the swelling appears in practically the same position, but the venous tumour is a little lower. If pressure is made on this tumour it immediately disappears and this occurs also if the patient lies down, especially if the leg is elevated In cases of small femoral hernia the tumour, which is usually produced by a piece of fat pushed through the femoral opening to become attached or strangulated, is often irreducible, does not disappear when the patient lies down, or when the leg is elevated If the dilated vein is emptied by pressure while the patient is standing the tumour immediately recurs when the pressure is released Both tumours give a sense of protrusion on coughing, but in dilatation of the vein a definite thrill is felt In operating on the patient mentioned the vein was doubly ligated close to its juncture with the femoral and then the operation for varicose veins was performed Most of the literature on this subject deals with cases in which a saphenous varix simulated a femoral hernia An article on this subject was written as long ago as 1836 by Boinet Thus not only may definite saphenous varix be mistaken for femoral hernia, but also dilatation of the upper part of the vein may

A DANGEROUS IMPERSONATION

ON Nov 28th, 1905, a man named Arthur or Charles Walters was sentenced by Mr. Justice Grantham to 12 months' hard labour for forging a death certificate in the name of Arthur Piercefield Walters, a duly qualified medical practitioner then residing in the Island of Eigg, but whose address was given elsewhere in the *Medical Register* and *Medical Directory* of that date The impostor was armed with the certificate of registration, birth certificate, and testimonials of Dr. A P Walters, whom he believed to be abroad It was the sagacity of the coroner in ordering an inquest, and the fact that the notice of the inquest in our columns came to the knowledge of the real Dr Walters, that resulted in justice being done We revive this ancient history, for it seems that the impostor is again at large It is reported in the daily press that a man, "described as a doctor, Arthur Percival Walters," was charged at Pontypridd last week with the murder of a single woman on whom he had performed an operation Fortunately, no confusion of identity need arise, for Dr Arthur Piercefield Walters's address is correctly given in the current Register and Directory. The incident may serve as a rather dramatic reminder to medical men of the need to keep their entries up to date, and that for public as well as private reasons

KROPOTKIN'S PHILOSOPHY

THERE is one aspect of the multifarious activities of Prince Peter Kropotkin, whose death has been announced on various authority and at different dates during the week, that has an abiding interest for humanity at large and for biologists in particular Kropotkin's view as to coöperative aid as an agent of social progress throughout the animal world was set forth in a memorable book, entitled "Mutual Aid" This was published in 1902, and combated what was then a popular conception that evolution meant simply the outcome of the struggle for existence Against this view Kropotkin set up the doctrine that evolution is mainly the outcome of mutual aid, of coöperation, and of social effort "The fittest are the most sociable animals, and sociability appears as the chief factor of evolution, both directly by securing the well being of the species, while diminishing the waste of energy, and indirectly by favouring the growth of intelligence" In this connexion it is important to note the full title of Darwin's epoch marking book, published in 1859, "The Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Existence," and also to note in what sense Darwin used the term "struggle for existence" He used it "in a large and metaphorical sense, including the dependence of one being on another, and including, which is more important, not only the life of the individual, but success in leaving progeny" By "favoured races Darwin meant those best suited to their environment, organic and inorganic, including food supply, shelter, climate, chances of mating, and, most important, maintaining offspring, he did not mean those which are best armed for the active destruction and extermination of their neighbours Darwin expressly states that when one species is more successful than another "we feel sure that the cause lies as much in one species being favoured as in another being hurt" But Darwin was also careful to point out the importance of sociability, sympathy and mutual aid, and mutual coöperation as factors in evolution, and in the "Descent of Man" many examples are given of how struggle is replaced by coöperation. "Those communities which include the greatest number of the most sympathetic members would flourish best, and rear the greatest number of offspring." Huxley at first failed to take this view, for he says: "From the point of the moralist, the animal world is on about the same level as the gladiator's show. The creatures are fairly well treated and set to fight, whereby the strongest, the swiftest, and the cunningest live to fight another day. The spectator has no need to turn his thumbs down, as no quarter is given." And again, amongst animals, as amongst primitive men, "life was a continuous free fight, and beyond the limited and temporary relations of the family the Hobbesian war of each against all was the normal state of existence." Kropotkin's "Mutual Aid" is the reply to the Nietzschean doctrine of power, and an appeal to the spacious ideas of Darwin's conception of the "struggle for existence." Moreover, he takes a wide view of evolution in respect to the social institutions of mediæval and modern times.

[1] Minnesota Medicine December 1920

SOLITARY CYST OF THE KIDNEY.

THE rarity of this condition, according to Dr. Herman L. Kretschmer[1] of Chicago, who records an illustrative case in a man aged 57, is shown by the fact that Simon found only 52 cases on record in 1906, since when Dr. Kretschmer has collected another 48. The condition must be distinguished from congenital polycystic disease and from the small cysts met with in chronic nephritis, with both of which some writers are apt to confuse it. An erroneous diagnosis is the rule, and in only two cases reported by Haenisch and Bockenheimer respectively was a correct diagnosis made before operation. Solitary renal cysts have very frequently been mistaken for lesions of other abdominal viscera, such as ovarian cysts, disease of the gall-bladder, enlargement of the spleen, mesenteric cysts or tuberculous peritonitis. In several instances, though the lesion was localised in the kidney, a diagnosis of tumour, hydronephrosis, calculus, or abscess was made. Nothing definite is known as regards the ætiology, but many authorities favour the so-called retention theory according to which the cysts are due to retention caused by obstruction. Solitary cyst of the kidney occurs most frequently after 30 years of age, although isolated cases have been reported in very young children. Of the 48 cases collected by Dr. Kretschmer 22 were females, 20 males, and in 6 the sex was not stated. Premonitory symptoms are often absent, and the presence of a tumour, as in Dr. Kretschmer's case, is the first thing noticed by the patient. Hæmaturia is an occasional but not frequent occurrence. The pain is that characteristic of the more common surgical diseases of the kidney. When the tumour reaches an enormous size its presence may interfere with the action of the bowels and lead to predominance of intestinal symptoms, such as flatulence and constipation. Dr. Kretschmer's case was characterised by a large solitary cyst and multiple cysts (four in number), and also by a double or bifid pelvis. At the operation at which nephrectomy was performed a single calculus was found in the upper pelvis, which was hydronephrotic. Both the calculus and hydronephrotic pelvis had been demonstrated by X rays prior to the operation. In other cases tuberculosis of the kidney, hypernephroma, horse-shoe kidney, and anomalies of the renal vessels have been found associated with solitary cysts of the kidney. As a rule, solitary cyst of the kidney is a unilateral disease, and is thus distinguished from congenital polycystic disease, which is always bilateral. In two cases, however, reported by Zaccarini and Cunningham respectively, cysts were present in both kidneys. In the remaining 46 only one kidney was involved, cysts being found in the right kidney 21 times and in the left kidney 20 times, the side not being stated in five cases. The size of the cyst varies from that of a hazel nut to that of a child's head. Its location is almost equally frequent in the upper and lower pole of the kidney. In most of the cases in which a mention of the contents is made they are described as clear serous fluid. In Dr. Kretschmer's case the large cyst contained old clotted blood and the smaller cysts clear straw-coloured fluid. In 16 of the 48 cases in his series nephrectomy was performed and in 18 either excision or resection of the cyst. Eleven cases were discovered only at autopsy and in one no mention is made of the type of operation. In one the sac was sutured to the abdominal wound.

NON-GONORRHŒAL BARTHOLINITIS.

AN abscess of the Bartholinian gland not due to gonorrhœa is so exceptional that considerable interest attaches to the case reported by Dr. H. Lippert,[1] of Elberfeld. His patient was a girl, aged 17, who had noticed a swelling of the left labium for about a week. She had never had any intestinal or bladder trouble, and there was no history of chill. Sexual intercourse was denied. Local examination showed well-marked œdema and redness of the left labium minus and some protrusion of the labium majus. Thick yellow pus was evacuated on pressure on the duct of the left Bartholinian gland. Nothing abnormal was found in the duct of the opposite side. The hymen was intact, and there was no discharge from the vagina or urethra. Microscopical examination of the discharge from the duct showed numerous leucocytes and a large number of bacilli, which cultures proved to be *B. coli*, associated with sarcinæ and non-specific cocci. No gonococci were found. Treatment consisted in dilatation of the duct and injection of 10 per cent. silver nitrate alternately with tincture of iodine. Recovery took place without incision. Dr. Lippert concludes by saying that [illegible] attention should be given to this form of Bartholinian abscess, as in a busy practice where there is no time or means of making an exact diagnosis, a patient may be wrongly suspected of gonorrhœal infection.

JOHN HUNTER AT "QUESTION TIME."

YOUNG men like a lecturer to be a dogmatist, and this John Hunter was not. His pupils, therefore, though they numbered among them Carlisle, Abernethy, Astley Cooper, and Chevalier—to name only a few of them—were never very numerous, and must often have been dissatisfied. It is known that Hunter permitted questions from his auditors, and often nonplussed them by the agnosticism of his replies. Several of these are classical, as when Astley Cooper asked with surprise whether a remark just made by Hunter were not a direct contradiction of something that he had stated a year ago, and the great man replied with admirable if disconcerting candour: "Very likely I did [say such and such a thing]; I hope I grow wiser every year." "Never ask me what I have said, or what I have written," he replied to another pupil, "but if you will ask me what my present opinions are I will tell you." To a pupil taking him at his word he nevertheless proved mystifying. This was Charles Brandon Trye, who afterwards became well known for his spirited defence of John Hunter, his master, against the scurrilities of Jesse Foot. Young Trye, in a very interesting MS. report of Hunter's lectures, copied by Charles Seager, F.R.C.S., about the year 1800, and now presented by his grandson, Mr. H. W. Seager, M.B., to the library of the Royal College of Surgeons of England, places it on record in a note that "I enquir'd of Mr. H. [with regard to his well-known definition of Life] if this did not make for the exploded doctrine of Equivocal Generation [Spontaneous Generation]. He told me perhaps it did, and that as to Equivocal Generation all we could have was negative proof of its not taking place. He did not deny that Equivocal Generation happened, there were neither positive proofs for nor against it." This was a singularly honest answer, and it would have delighted Professor Huxley a century later. It was not, however, what a young and ardent admirer had a right to expect. Trye was evidently under the impression that John Hunter lectured in order to state definite truths, and accordingly he arranged his notes of the lectures in a series of aphorisms, in number 1754. He abandoned Hunter's exact phraseology. "I forsook," as he says, "any attempt of following either the language of the lecturer (except in terms of art) or the arrangement of his matter, ... only attempting to give a faithful representation of his lectures according to the sense in which I understood them at the time they were delivered, and the best information I could procure from my fellow pupils on the subject." As a matter of fact, Hunter did not set out to lay down the law; he was, as Palmer points out, advancing paradoxes, starting novelties, and, indeed, inaugurating a revolution in surgery. He was thus often as much a seeker and a questioner as his pupils.

THE ABDERHALDEN REACTION.

THE history of the Abderhalden reaction, if written, will make an interesting study in medical science, illustrating the dominance of German opinion in Europe and America until quite recent times. The reaction was first announced as a method for the early diagnosis of pregnancy, but it was quickly applied to the diagnosis of disease and apparently with astonishing success. Other serum diagnostic methods were eclipsed. The reaction became not merely a means of diagnosing diseases the morbid anatomy of which was well understood—for example, tuberculosis or cancer—but it also became an instrument by means of which hypotheses and theories could be put to the test. Obscure nervous maladies have been investigated with a view to the discovery of causes, the result being generally that glands with internal secretions are found to be at fault. Instances of this chain of doubtful evidence are provided in a book recently published by Dr. Gottfried Ewald.[1] The author devotes the first 80 pages of his book to a discussion of the ideas underlying the Abderhalden method of diagnosis—namely, the development of protective ferments in pregnancy and in disease; their origin, nature, and specificity; and the practical methods employed to demonstrate their existence. The remainder of the book deals with the application of the knowledge gained in the author's special domain of medicine, psychiatry. The copious references—289 in number, as well as half a dozen special treatises on the subject, all German—show in what a continuous stream papers on the subject poured out from German laboratories and clinics. Authors appeared who could distinguish between pyloric and duodenal ulcers by a comparatively simple examination of the patient's blood serum. There was obviously a flaw somewhere, or the study of disease was less difficult than most people had formerly thought; and it now seems clear that Abderhalden's original work, on the appearance of protective ferments, was not sound, and had been received with a too easy credulity by the medical scientific world. Competent observers in this country and in America have been unable to verify the results of Abderhalden's primary experiment; for example, Dr. W. E. Gye, in a critical study made at the Imperial Cancer Research Fund, found it impossible[2] to produce in rabbits by injection of raw egg-white a ferment which digests coagulated egg-white. Given a false premiss, the rest does not arise, and a special treatise on the subject has no practical value. Perhaps some day the information that the whole superstructure is a mistake will leak through into Germany, and the enviable capacity of German scientists for continuous intellectual effort will be directed along more fruitful lines.

TREATMENT OF THE WOUNDED AND MUTILATED IN FRANCE.

ACCORDING to the French Law of March 31st, 1919, all who were wounded, mutilated, or otherwise injured during the war are entitled to receive gratuitously, for the rest of their lives, whatever medical treatment their injuries may render necessary. An announcement, however, has just been published to the opposite effect. In consequence of difficulties with the Government, the Union of the Medical Syndicates of France insists that, from the Feb. 1st next, all the war victims must pay the usual medical fees. Needless to say, this bare statement caused considerable resentment, for it was naturally felt that those who have suffered for their country merit less cavalier treatment. We are pleased, therefore, to be able to show that there is no ground of complaint against the medical profession. A frequent correspondent on French affairs writes: "The wounded have been well treated throughout, and it is the medical practitioners who have good cause for complaint. As matters now stand, a former soldier invalided and discharged because of wounds received, is given a book at the town hall of his district which he presents to the practitioner he choses to consult. The latter tears out a coupon from this book for every consultation given, and this coupon is supposed to represent a fee which the local authority should pay. As a matter of fact, hardly any such payment has been effected. Therefore the medical syndicates now propose to reverse the process. They suggest the patient should pay the fee, and the practitioner will give the patient the coupon, who will present it where it has to be met. It is no part of medical practice to spend time in going from office to office to obtain the reimbursement of coupons." The French Minister of Pensions, in face of the situation, has announced, we learn, that a syllabus of regulations will soon be issued dealing with the position and some other matters germane to it. There is notably the question of the amount of the fees that so far have been rarely paid, and then vaguely according to local custom. But local custom varies very considerably, if for no other reason than that the cost of living is about double as much in Paris as, for instance, in the department of the Basses-Pyrénées. The Government naturally would find it much easier to fix a uniform fee for the whole country, though in practice it would mean that those who were in the greatest need would receive proportionately less than those who were better off. Then there is the delicate question of so organising medical relief that it shall not appear as a sort of poor relief. The soldiers, officers and men, who have suffered for their country are entitled to assistance as a matter of right; they have more than earned it, a fact none are more ready to acknowledge than the medical profession itself. Of this generous and grateful disposition the best proof is that, since the enactment of the Law of March 31st, 1919, the medical profession have willingly given their services to the patients in question and, as a rule have not received any remuneration. But it is the State and not the doctor who is indebted to the soldier; the whole nation and not merely the medical profession has to show its gratitude.

WE regret to record the death of Dr. J. C. McWalter, barrister-at-law and high sheriff of Dublin. Dr. McWalter held three M.D. diplomas, those of Dublin (R.U.I.), Durham, and Brussels, and was the recipient of honorary degrees from Dublin, Ottawa, and Alberta Universities.

THE last number we have received of the *Annali di Medicina Navale* brings the regrettable news of the retirement of the Director-General of the Italian Navy, Surgeon Lieutenant General F. Rho, well known for his scientific medical investigations. Of all medical directors general of navies and armies he had the greatest record of scientific work done and published, these officers being usually chosen rather for administrative ability.

TUBERCULOSIS.

A Census and Survey of Tuberculosis.

THE plan, which seems to have first been devised by Framingham in the U.S.A., of taking a tuberculosis census of a community and conducting a hustling, comprehensive campaign against this disease, is being adopted by other corporate bodies, and the results of such a survey have just been published[1] by the health authorities of Cleveland. It is at present impossible to calculate the exact value of these surveys; undoubtedly they provide useful information, but if this is to be of real value it requires careful sifting and discriminating judgment, for in no disease so much as in tuberculosis is the relation of cause to effect so liable to be misunderstood. And even if the numerous data collected are sorted out in proper perspective, and correct conclusions are drawn therefrom, the adoption of the measures indicated is still apt to be neglected.

Incidence of tuberculosis in Cleveland.—In Cleveland, with a population of about 800,000, between 1000 and 1200 persons die annually of tuberculosis, and nearly 6000 cases occur. At present from 20 to 30 per cent. of all the cases of tuberculosis are not notified before death, and a search for active cases revealed a ratio of 4·7 to every annual death. It is admitted that this ratio is misleading, for in Framingham the search for active cases was so productive that it showed a ratio of approximately nine living cases to one death per annum. Another discovery reflecting on the inadequacy of the present methods of diagnosis is the fact that 50 per cent. of all the cases were in an advanced stage of the disease when first diagnosed. This proportion, it is calculated, could be reduced at least to 25 per cent. by the exercise of greater care and skill on the part of general physicians. In Framingham, on the other hand, the high standard of diagnostic skill has led to 74 per cent. of all the cases being detected in the first stage of the disease. Framingham, by the way, is frequently held up as a model and a standard for comparison in the matter of prevention and early diagnosis.

Milk-supply and tuberculosis.—An attempt was made to study every aspect of the milk-supply of Cleveland as far as it concerned tuberculosis. According to the laws already in force, all certified milk must be obtained from tuberculin-tested and negatively reacting cows, from regularly inspected establishments, and handled by medically inspected employees. All milk must be sold according to specified grades, and all uncertified milk must be pasteurised. So far, so good. But these legislative measures do not, and cannot, control the amount of milk consumed, and it was found that only 44 per cent. of the amount of milk considered desirable was consumed. The actual figures were 1·61 quarts per day for a family of 3·1 children, whereas the estimated quantity considered necessary for a family of this size was 3·6 quarts.

Want of specialists.—Scattered throughout this report are reflections on the quality of the medical and nursing staff engaged on tuberculosis work. It is, apparently, difficult to secure enthusiastic and specially trained physicians for tuberculosis work in the dispensaries. The physicians are for the most part men with no special training, and their work is part-time and receives only part of their interest. The nurses, too, are given tuberculosis work only as a part of their total work, and it is admitted that some public health representatives in Cleveland find that tuberculosis work has suffered from the want of specialisation. But, it is added, there are many advantages to offset the defects of the "generalised" nursing system.

Bureau of statistics.—This department is mentioned only to be vigorously criticised. It provides a very indifferent service, it has no full-time chief, and the methods of developing statistical data seem to be informal and haphazard. No effort is made in the study of tuberculosis mortality to eliminate non-resident deaths and to include the deaths of residents dying out of town. It is evident from criticisms such as the above that the authors of this survey do not feel con[illegible]ed to include "whitewash" in their equipment.

Recommendations.—An aggressive campaign of industrial hygiene to promote the education of employers and employees alike is recommended, as well as the linking up of medical, nursing, and clinical facilities with industry. The routine examination of employees for early signs of disease, and the consistent supervision of arrested cases after return to industrial pursuits are urged as of great importance. Other recommendations are: promotion of home hygiene, preventorium activities, such as summer camps, and possibly the socialisation of the milk-supply. With reference to sanatorium beds which remain empty, and to the premature discharge of patients at their own request, an extensive popular educational campaign is advocated, as well as the appointment of only highly qualified medical officers to sanatoriums. The calculation is made that at least one bed should be provided for every annual death from tuberculosis—a standard which would necessitate the present number of beds in Cleveland being approximately doubled. It is customary in Cleveland for arrested cases to be observed for a period of only six months. This, it is admitted, is far too short. Brief as is this summary of the Cleveland Survey, it shows that the authorities of a progressive community are attempting to set their house in order with thoroughness and impartiality.

Fall of the Tuberculosis Death-rate in Germany.

Professor B. Möllers[2] of Berlin has come to the conclusion that 1918 marked the culmination of the upward wave of tuberculosis in Germany, and that the subsequent ebb shows signs of being rapid. He calculates that, as a result of the war, German towns with a population of 15,000 or more lost approximately 100,000 more inhabitants from tuberculosis than they would have done had the death-rate of 1913 been maintained throughout the years of the war. As his tables show, the mortality in the first half of 1914 was 1·75 per 1000, in the first half of 1919 it was 3·44 per 1000, and in the first half of 1920 it was only 2·08 per 1000. He also calculates that in the first half of 1919 the death-rate was 97·1 per cent. higher than in the first half of 1914, but that in the second half of 1919 this excess over the figures for the corresponding period in 1914 was only 36·3 per cent., and in the first half of 1920 only 18·9 per cent. higher.

Prevention of Tuberculosis at Sea.

It has long been admitted that the conditions under which Norwegian fishermen lived in motor-boats were most unhygienic, and reports were frequent of able-bodied fishermen going to sea for some weeks in these motor-boats and returning home with tuberculosis. In 1913 the Norwegian National Association for Combating Tuberculosis took up this matter, and through the Ministries of Health and Shipping it succeeded in introducing far-reaching reforms, which came into force in December, 1919. To judge by the account given in *Tidsskrift for Den Norske Laegeforening* for Nov. 15th, 1920, these reforms were badly needed and much overdue. As many as five to six men had often to spend the day and night in a tiny cabin in which they had to dry their clothing, reeking with fish offal, as well as cook and eat their food. The floor was bespattered with tobacco juice and fish debris, and there was little or no ventilation for the mixed odours of tobacco-smoke, bilge water, cooking food, fish offal, and the ship's engine. Thanks to the initiative and hustling vigour of the National Association, numerous regulations were drawn up to mitigate these insanitary conditions. It is now incumbent on the owners of fishing boats to renovate (paint) their cabins once a year, to prevent pollution by bilge water and cargo of the air in these cabins, to clean the ballast and bottom of the boat at the end of each fishing season, to provide adequate ventilation for each cabin as well as lighting, to supply a berth of sufficient size to each sailor, and to fit banisters or handles to steps going down to a cabin so that sailors do not have to grip with their hands the steps which they have soiled with their feet. The National Association took steps last summer to prevent the lapse of these reforms to a dead letter.

---

[1] and Hospital and Health Survey: Tuberculosis, Part 4, 50c.

[2] Deut. Med. Woch., Jan. 6th, 1921.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Statistics on Suicide in 1920.

A REMARKABLE drop in the number of attempted or committed suicides was noted during the years of war. Whilst in 1913 it was about the same as a year ago—viz., 1500—in 1915 it fell to 881. The figures for the next three years were 842, 804, 700. In 1919, the first year of peace, the figure rose to 1138 cases; in 1920 there were 1189. The highest number—50—occurred as usual during May. The favourite means adopted was, as it has been for many years, hanging (122 persons). Poisoning comes next, with 51 men and 67 women, totalling 118. Suicides by shooting, 80 (65 men, 15 women); by jumping from windows, 57 (13 men, 44 women); 53 persons (28 men, 25 women) threw themselves into water. Injuries inflicted by sharp instruments, by throwing oneself before a vehicle, or by burning were chosen only in a few instances. The age record was 85 years; a man who hanged himself heads the list. A pleasing feature to be noted is the absence of children's suicides for two years.

Mr. Rockefeller's Gift to the Medical Faculties of Austria.

A representative of Mr. Rockefeller called recently upon Professor Haberda, the dean of the Medical Faculty of Vienna University, and informed him that he had been instructed by his principal to present a sum of 20,000 dollars to each of the universities of Vienna, Graz, Innsbruck, Prague, and Budapest. The money is to be devoted solely to the procuring of materials necessary for medical apparatus and laboratories, and the donor has stipulated that an equal sum be raised by the faculties themselves. But it is impossible in this country to get together such a large sum from the funds at the disposal of the universities; nor is it possible to make the students pay fees high enough to reach these figures. Therefore it was arranged, with the consent of Mr. Rockefeller or his representative, that the foreign students, who on account of the exchange value of their money are able to pay high fees, be taxed in order to increase the revenue of the University. Thus, from February they will have to pay a sum of Kr.20 a month for using the University laboratories, apparatus, &c. Nevertheless, it is feared that it will be impossible even by these means to equal the sum of Mr. Rockefeller's gift.

Opening of New Hospitals in Vienna.

Within the last few months a number of new hospitals were opened in this city, or in its vicinity, in spite of the precarious state of the municipal finances. A new building, accommodating 500 patients, situated in extensive grounds and offering ample opportunity for garden work and agricultural occupation, has been devoted to the treatment of venereal diseases of females. Here the patients will also be given psychical treatment, which will no doubt be badly needed by the prostitutes and others who will enter the hospital. Another new hospital, also for 500 patients, containing wards for medical and surgical cases and out-patient departments for diseases of children, eye diseases, and oto-rhino-laryngological work, will be opened shortly on the outskirts of the city, where it is much needed. A special hospital for the study of nervous diseases and conditions like speech-disturbance and writers' cramp has been attached to one of the institutions set apart for shell-shocked cases and injuries to the head. Owing to the munificence of a Swedish committee an institution accommodating 100 tuberculous patients has been erected on a mountain slope not far from Vienna; there the patients, who will mostly be children of the middle classes stricken with the "morbus Viennensis," as tuberculosis is here termed, will be received for a period of not less than three months each. Ample opportunity for treatment by open air as well as by sunlight and electricity is there given. Another special hospital in Baden, a suburb of Vienna, formerly an army hospital, has now been converted for the treatment of rheumatic diseases. In this institution three hot sulphur springs (known to and used by the Romans) are utilised, in combination with massage, modern gymnastics, and electro-therapeutics. The results obtained in this up-to-date hospital are most gratifying both to patients and staff.

Epidemic of Hiccough in Austria.

From various parts of the country, both rural districts and towns, there come reports of an epidemic characterised by persistent and tormenting attacks of hiccough. As a rule these attacks are preceded by an ordinary cold, by bronchitis, cold in the head, "influenza," or the like. Disturbances of the gastro-intestinal tract are rarely the predisposing cause. The age-incidence is not of importance, as both infants and elderly people are affected. Severe exhaustion, giving rise to anxiety, is not rare; in debilitated persons attacks of heart failure sometimes occur after persistent hiccough. The fits last from a few seconds, with short interruptions, up to hours; they generally cease after 5–6 days, leaving the patient very much prostrated; recovery is generally uneventful and rapid. Treatment must be confined to symptomatic remedies—bromides, morphia and its derivatives, care of the heart, and frequent though small quantities of food are very useful. The ætiology is up till now a mystery; no definite micro organism or nervous condition can be held responsible for the affection.

Experiments on the Effects of Saccharine.

Owing to the distribution of saccharine instead of sugar by the Government to the public, reports of its harmful effects were circulated by persons interested in the sale of sugar. Therefore a large number of experiments were conducted, and compared with other results obtained in the Government saccharine factories. An official announcement was then made to the effect that for the 30 years during which saccharine has been produced by Austrian factories not a single case of harmful effect has been known; that saccharine has been shown to be quite indifferent, of no food value, but passing through the body without any noticeable action. In physiological experiments one person has been given up to 100 g. of saccharine (equal to 55 kilos of sugar in sweetening power) within one day without any undesirable effect, and in another series of experiments as much as 500 g. of crystalline saccharine, equal to 220 kilos of sugar, had been given to one individual within nine days, also without any effect. It was also pointed out that diabetic persons frequently take large quantities of saccharine for years without suffering any harm, that saccharine is to be compared to a condiment, but that it is of course important that the product be absolutely pure.

SWITZERLAND.

(FROM OUR OWN CORRESPONDENT.)

Foot-and-mouth Disease.

Foot-and-mouth disease has assumed considerable importance in this country. It can be called now epizoötic. Some time ago the disease was the subject of discussion at a joint meeting of the Medical Society and Veterinary Society of Berne. Berne is the centre of one of the most important agricultural districts of Switzerland, therefore the problem has aroused considerable interest. The following facts seem to be the most noteworthy features of that discussion. During the last century several epidemics have been recorded, the most serious after the Franco Prussian War of 1870–71. The opening of the different transalpine railways has greatly augmented the dangers of infection, therefore a limited number of frontier stations have been designed for the import of cattle which are provided with permanent official veterinary surgeons to secure control. It has been ascertained that the present epidemic found its way into Switzerland from Italy, the first outbreaks being recorded in the canton Ticino and in the Gruyère district. Although all transport of cattle was stopped at once the disease spread rapidly, a proof that there are carriers of the most different kind. It is probable that man is one of them. Amongst game, especially deer and chamois, the disease has never been found. The policy for combating the disease has been roughly the following. Once the nature of the disease is established all the cattle of the farm are slaughtered immediately on the spot. In the neighbouring area all movements of animals are strictly prohibited. The affected centre is isolated for six weeks. The stables are thoroughly disinfected; dogs, cats, pigeons, crows, &c., around the house are killed by the police. At a later period of the epidemic wholesale slaughtering has been given up and more attention has been paid to the movements of man. Pastures were declared prohibited area. In some parts of the country the travelling public had to submit to some measures of disinfection—e.g., the footwear had to be washed in a solution of lysol and the clothes were sprayed with corrosive sublimate. Some of these measures had not been ordered officially but were carried out by the farmers in self-defence. As their application was clumsy, and in some cases so unscientific as to be humorous, the effect was nil.

In some districts the local authorities went so far as to interfere with the railway and road traffic, not only after the outbreak of the disease, but in some cases as a measure of prevention. These things became a public nuisance so that the Federal Government had to intervene and to enforce some general principles for combating the disease. Happily the slaughtering had little or no influence on the milk production. Of the 800,000 milch-cows of Switzerland only 8000 were slaughtered during the year.

Of the pathology of the disease the following points seem to have been elucidated. The cause is a filtrable virus, the resultant immunity is of a very short duration, the same cattle may have the disease three or four times during one year. Experiments have shown that meat and blood from infected cattle is not infectious. The town of Berne consumed for a long time practically exclusively meat of infected cattle. The milk is, on the contrary, contagious. The question of foot-and-mouth disease in man is still open for discussion. It appears that so far no cases have been recorded in Switzerland, where the diagnosis had been surely established. Statistics have shown that outbreaks of aphthous stomatitis amongst children do not occur synchronously with foot-and-mouth disease in cattle. The contrary, I understand, prevails in Great Britain.

Scientific knowledge of the disease is still very small, and therefore doctors and veterinary surgeons fight in the dark. Some months ago the Federal Government nominated a strong committee of leading clinicians and pathologists, both human and veterinary, to investigate the causes.

Feb. 3rd.

THEORY OF RELATIVITY.—A special issue of *Nature* on Feb. 17th will contain an authoritative scientific statement on relativity from different points of view. The 14 articles will include: A Brief Outline of the Development of the Theory of Relativity, by Professor A. Einstein; Electricity and Gravitation, by Professor H. Weyl; Theory and Experiment in Relativity, by Dr. Norman R. Campbell; the Metaphysical Aspects of Relativity, by Professor H. Wildon Carr; the Relativity of Time, by Professor A. S. Eddington, F.R.S. A bibliography of books and pamphlets on relativity will conclude the issue.

BROMPTON HOSPITAL AND THE L.C.C.—The relations between the Brompton Hospital and the London County Council have been made the subject of comment. *The existing arrangements are that the Council send a* certain number of patients to the hospital and to the sanatorium at Frimley. Those sent to the hospital are chiefly for observation and diagnosis. When the latter is established, recommendations are made as to future treatment by the honorary staff. Certain of the medical officers of the Council visit the hospital regularly to [illegible]rate with the staff in regard to these recommenda[illegible] A permanent scheme is under discussion.

Public Health.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

PADDINGTON: 1914–18, INCLUSIVE.

Dr. R. Dudfield issued his last report for the year 1913, and has decided to issue the reports for the following seven years in two volumes, the first to cover 1914-18 and the second to serve for 1919 and 1920. In a preliminary statement he points out that the mortality tended to increase with the prolongation of hostilities, and that this was more particularly observable in the mortality at ages under one year; that the only disease which left an outstanding record during the war was influenza; and that at the close of the war there were considerable arrears of sanitary work to be cleared off.

The population estimates being very vague he has thought it wise to adopt, instead of rates, a comparison between the actual deaths and births of the quinquennium 1914–18 with those of the preceding quinquennium 1909–13. As the population was a slightly decreasing one up to 1914 this method ought to give results not dissimilar from the comparison of rates. The number of births has decreased from 3031 in 1909 to 2017 in 1918, a fall of 33·5 per cent. The percentage of illegitimate to total births has increased from 6·17 in 1914 to 10·41 in 1918. An interesting change has taken place in midwifery practice. In 1914 little more than one-third of the births were notified by midwives, whereas in 1918 the midwives reported 61 per cent. Will the change be temporary or not?

The total deaths for the war quinquennium were 9·3 per cent. higher than for its predecessor. Dr. Dudfield ascribes the relative immunity of the country from enteric fever and small-pox to the high standard of the preventive medical service in the army and the vigilance of the port sanitary service. He emphasises the value of inoculation for preventing enteric fever, and at the same time points out that the proportion of unvaccinated children in Paddington has risen from about 10 per cent. at the beginning of the century to about 30 per cent. during 1917 and 1918, and that "at no very distant date the proportion of the unprotected to the total population will become so large that small-pox will not be kept in check by the vigilance of health officers." In Paddington during the war quinquennium there was an appreciable increase in maternal mortality from puerperal fever and accidents and diseases of parturition. There was also some increase in the notifications of ophthalmia neonatorum. The number of notifications is not a very reliable guide to the prevalence of this disease, and it would be interesting, if it were possible, to have the cases followed up and the amount of the damage to the eyes recorded. Deaths from pulmonary tuberculosis in Paddington showed a 10 per cent. increase for males and a 20 per cent. increase for females during the war years. This is in accord with the experience of other towns. A table is given showing that the deaths from pulmonary tuberculosis occurred at earlier age-periods among women than among men. Attention is drawn to the large number of deaths from tuberculosis of persons who had not been notified during their lifetime. Thus, no less than 64 persons died in their homes in the borough and 32 in local institutions without being notified. The fact that 54·4 per cent. of the cases of pulmonary tuberculosis died in institutions, as compared with 48·3 per cent. in pre-war years, indicates progress in the segregation of advanced cases.

The comparison between the two quinquennia shows a rise in infant mortality from 106 to 109. "Of 1016 illegitimate children born during 1914–18 263 died within the first year of life—equivalent to a mortality of 258 per 1000 births, as compared with 96 among legitimate children." This very high "illegitimate" mortality is somewhat lower than in 1909–13. Perhaps the worst features in the child mortality are the increases in the deaths during the second, third, fourth, and fifth years of life, when comparison is made with the previous quinquennium These increases are shown by Dr Dudfield to be 12 per cent for the second year, 21 per cent for the third year, 70 per cent for the fourth year, and 7 per cent for the fifth year.

We now turn to the administration section of the report The author says "The need of inspection for the discovery and remedy of sanitary defects was greater at the end of 1918 than it had ever been before' The *report describes the flooding with sewage caused by* the rainfalls of June 16th and June 28th, 1917, at the rate of 1 04 inches and 0 75 inch per hour respectively The *smaller number of children of school age found* on the canal boats seems to indicate that their education is receiving more attention. In Paddington, as elsewhere, the black smoke nuisance was left alone during the war owing to the bad class of fuel available, and to the skilled stokers being wanted for the services As dense black smoke from chimneys serving boiler furnaces is quite unnecessary, it is much to be hoped that this neglected matter will be taken up in all parts of the country with vigour Dr Dudfield points to the need for a much more close inspection of the tenement houses—the bugbear of sanitary reformers in every town—and for the resumption of the "annual cleansings"

The report on the Sale of Food and Drugs Acts shows the extremely unsatisfactory state of the milk supply. The percentage of adulterated samples taken at the railway stations ranged from 40 to 50 during the war years The position of the "preservatives in foods" question is pointed out, and examples are given of sausages with over 11 gr of boric acid per lb, lime juice cordial containing over 11 gr per pint of salicylic acid, brawn with over 11 gr per lb of boric acid, &c, and it is suggested that the legislature should settle when (if at all), and in what quantities, these additions to food should be permissible

We look forward with interest to Dr. Dudfield's second volume dealing with the two post war years

URBAN VITAL STATISTICS

(Week ended Feb 5th, 1921)

English and Welsh Towns—In the 96 English and Welsh towns, with an aggregate population estimated at 18¼ million persons, the annual rate of mortality, which had been 12 8, 13 3 and 12 3 in the three preceding weeks, rose to 13 1 per 1000 In London, with a population of 4½ million persons the death rate was 13 3, or 1 7 per 1000 above that recorded in the previous week, while among the remaining towns the rates ranged from 5 8 in Rotherham, 6 5 in Acton, and 6 9 in Cambridge to 20 1 in Warrington, 20 7 in West Hartlepool, and 26 8 in Tynemouth The principal epidemic diseases caused 238 deaths which corresponded to an annual rate of 0 7 per 1000 and comprised 82 from infantile diarrhœa, 65 from diphtheria 56 from whooping cough, 19 from measles 14 from scarlet fever, and 2 from enteric fever Whooping cough caused a death rate of 2 0 in Warrington and 2 3 in Wigan, and diphtheria of 1 9 in Ilford There were 4018 cases of scarlet fever, 2767 of diphtheria and 1 of small pox under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 4171, 2682 and 1 respectively at the end of the previous week. The causes of 36 of the 4649 deaths in the 96 towns were uncertified, of which 12 were registered in Birmingham, and 3 each in London, West Bromwich, and Leicester

Scottish Towns—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2½ million persons the annual rate of mortality, which had been 15 9, 15 8 and 16 3 in the three preceding weeks, fell to 14 9 per 1000 The 307 deaths in Glasgow corresponded to an annual rate of 14 5 per 1000 and included 16 from whooping-cough, 9 from infantile diarrhœa 4 from diphtheria, and 1 from scarlet fever The 148 deaths in Edinburgh were equal to a rate of 17 3 per 1000, and included 2 each from scarlet fever, diphtheria, and infantile diarrhœa and 1 from measles

Irish Towns—The 114 deaths in Dublin corresponded to an annual rate of 14 1, or 1 7 per 1000 below that recorded in the previous week, and included 3 from diphtheria, 2 from infantile diarrhœa and 1 from scarlet fever The 114 deaths in Belfast were equal to a rate of 14 2 per 1000, and included 6 from whooping-cough, 2 from diphtheria and 1 from infantile diarrhœa

The Services.

THE ARMY DENTAL CORPS

AT the outbreak of war there was no adequate provision for dental services to the troops and this was keenly felt by those forming the original Expeditionary Force The need for such service was early recognised by those in authority, and in October 1914 a commencement was made by the appointment of six dental surgeons With the growth of the Army the dental service was increased, and at the time of the armistice commissions were held by over 800 dental surgeons It is universally acknowledged that the work of these officers added to the efficiency of the forces, and with the return of the Army to a peace basis the Government has wisely decided to form an Army Dental Corps The number of officers has not been stated, but we feel sure with the experience gained in the war an adequate service will be provided It is possible that when these data are forthcoming there will be some who consider the number insufficient, but in any criticism that may be offered due consideration should be taken of the difference between an Army on a war or a peace basis In peace time the medical examination is more searching, and only those dentally fit or able to be easily rendered dentally fit are accepted Further, we believe that there is an Army Order stating that no man requiring dentures can be recruited Under these conditions the appointment of one officer for each 2000 men should be sufficient The rank of officers in the corps is to range from lieutenant to lieutenant colonel and the pay, although on a slightly lower scale than that of the Royal Army Medical Corps, should be sufficient to attract the right type of officer *The formation of an Army Dental Corps* is a distinct step in the right direction, and no doubt a scheme will gradually be evolved for its rapid expansion in the event of war Provision will be needed for the Territorials and for a reserve of officers Arrangements will, we assume be made to enlist the services of the dental schools with their well equipped laboratories

ROYAL NAVAL MEDICAL SERVICE

The following appointments have been notified: Surg Cmdrs J H Lightfoot to *Conqueror* J Bojan to *Defiance*, C T Baxter to *President* additional for R N Recruiting Headquarters

Surg Lieut Cmdr F C Wright to *Birmingham*

Surg Lieuts F L H MacDowel to Haulbowline Hospital and Dockyard and J C Brown to Special R M Battalion

ARMY MEDICAL SERVICE

Col S L Cummins retires on retired pay

TERRITORIAL FORCE

Major Sir R Jones from 1st Western General Hospital to be Colonel and to be granted the honorary rank of Major-General

ROYAL ARMY MEDICAL CORPS

Lieut Col P S Lelean to be Brevet-Colonel

The undermentioned *Majors to be Brevet Lieutenant Colonels* R M J Perry and (Acting Lieut Col) W P MacArthur

Lieut-Col M P Corkery is placed on the half pay list on account of ill health

Major H G Pinches retires on retired pay and is granted the rank of Lieutenant Colonel

Captains to be Majors (Bt Majors) J A Manifold P S Tomlinson M J Williamson S S Dykes W H O Riordan C F V Benson (Acting Lieut Col) W P MacArthur (Acting Major) R C Priest (Temp Major) A D Stirling G I Taylor R C Paris F C Lambkin O W McSheehy C L Franklin M White J J D Roche H F Joynt A S M Winder H R Edwards J R Yourell P G M Elvery J J H Beckton W B Rennie and W Mathieson

Capt L F K Way retires receiving a gratuity and is granted the rank of Lieutenant Colonel

Temp Capt W L Hay relinquishes the acting rank of Major

To be Temporary Captains F W Harlow (late temporary Captain) and Temp Lieut O T J C de H Clayre

The undermentioned Lieutenants (temporary Captains) to be Captains P A Stewart J C Collins W I FitzG Powell G W B Shaw and W C Mackinnon

TERRITORIAL FORCE

Capts R G Badenoch and A Robertson to be Majors

Majors J L Menzies (late R A M C) and P J Gaffikin (late R A M C S R) to be Captains and relinquish the rank of Major

Capts H W Featherstone (late R A M C, S R) and T Carnwath (from T F Res) to be Captains

Capts (Acting Lieut Col) J R Pooler and (Acting Major) W C Gunn relinquish their acting rank on ceasing to be employed

Capt A C Wallace resigns his commission and is granted the rank of Major

Capt J H Barclay resigns his commission and retains the rank of Captain

Capt T D Webster (late R A M C) to be Lieutenant and to relinquish the rank of Captain

Second Lieut R J Dyson (from T F Res W York Regiment) to be Lieutenant

Correspondence.

"Audi alteram partem."

THE DIET OF WELL-TO-DO CHILDREN.

To the Editor of THE LANCET.

SIR,—In connexion with the correspondence on this subject appearing in THE LANCET, may I direct attention to the effects on the gastro-intestinal tract of deficient and ill-balanced foods? In my experience the commoner food faults among the children of the well-to-do are (*a*) an insufficient supply of vitamines—rarely their complete absence; (*b*) a disproportionate richness of the food in carbohydrates, and, when the provision of fresh fruit and green vegetables is scanty and the milk has been super-heated, an insufficient supply of salts—notably of calcium.

The effects of such faulty food, as I have observed them in wild monkeys under experimental conditions, are the following:—(1) Congestion of, and hæmorrhage into, the walls of the stomach and intestine; (2) atrophy of the myenteron; (3) degenerative changes in the ganglionic plexus of Auerbach; (4) dilatations of various parts of the tract; (5) increased tendency to intussusception; (6) inflammatory states, especially of the colon; (7) invasion of the bowel walls and the adjacent lymphatics by intestinal bacteria; and (8) depressed functional activity of the digestive glands. The severity of these changes is dependent upon the degree of avitaminosis, the character and extent of the ill-balance of the food, and the duration of the animal's subjection to it. The more immediate clinical evidences of gastro-intestinal derangement are loss of appetite, anæmia, vomiting (occasionally), digestive disturbances, and diarrhœa; the more remote are distended abdomen, profound anæmia, "air-locks" in the small bowel, dilatation of the stomach and colon, and colitis—the last one of the commonest manifestations of deficient feeding.

There can, I think, be little doubt that the pathological changes above referred to, especially those involving the neuromuscular control of the bowel, afford reasonable ground for attributing to the long-continued use of deficient and ill-balanced food an important part in the production of gastro-intestinal stasis. These changes are similar to those found by Professor Arthur Keith in the colons removed from sufferers from this disease at operation. A contributory factor in their production is the depressed functional activity of the endocrine organs—notably of the suprarenal glands, the pituitary body, and the thyroid gland—which results from the same cause. The interdependence of healthy gastro-intestinal function and efficient endocrine action is so well recognised as to call for no further comment.

I am, Sir, yours faithfully,

Oxford, Feb 4th, 1921. R. MCCARRISON.

REFERRED PAIN.

To the Editor of THE LANCET.

SIR,—In the discussion which centres around the question of referred pain and the viscero-sensory reflex, one simple observation seems almost invariably to escape remark, both by the champions of the viscero-sensory reflex and by those who are not so greatly impressed with its importance. It is that *the superficial hyperæsthesia which constitutes the reflex is only present during the presence of pain or for a limited period thereafter.*

To take the instance of a gastric ulcer, it will be readily accepted that in the majority of instances—especially in hospital and consulting practice—we visit, or are visited by, sufferers from ulcer at a time when they are free from pain. At these times the reflex is usually absent, and most of us have consequently come to regard local superficial hyper[illegible]thesia as an uncommon sign and of slight [illegible]stic value. If, however, the patient is seen during an attack of pain, or within a variable, but limited, time after the pain, hyperæsthesia is more often present and its location may well help to establish a more accurate diagnosis. In other words, it is not the presence of the ulcer but of the pain consequent upon the ulcer which is the stimulus for the reflex. The patient himself quite frequently volunteers a remark which seems to bear out the truth of this observation, for he may tell us that he cannot bear the touch or friction of his clothes over the skin of the epigastrium in the neighbourhood of the period of his worst pains. It has long been recognised that anginal referred pain and tenderness of skin and muscle are present only during, or for a short time after, the attack, and no one would, I think, maintain that the sign was to be elicited in the sometimes long intervals between the attacks. In other words, it is not the presence of a cardiac lesion, but of cardiac pain, which serves as the stimulus for the reflex. We must also recognise that the stimulus is not, whether in quantity or quality, always adequate to produce the reflex, and that in this respect the viscero-sensory reflex does not differ from other established forms of reflex action.

In each of the cases described by Dr. A. Murdoch in his letter in to-day's issue of THE LANCET the factor of recent pain—though in the second case Dr. Murdoch refers to the manipulation as supplying "the necessary stimulus"—was present. In this second case the factor of recent pain was, on the occasion of the examination by Mr. D. Ligat, absent, and so, naturally, was the reflex. In Dr. A. F. Hurst's 10 cases it would be important to know whether pain was a present or recent symptom at the time of application of the test.

I believe the foregoing to be a correct statement of the facts of referred hyperalgesia in visceral disease, and an explanation also of the existence of the two camps which contend on the one hand that viscero-sensory reflexes are of considerable, and on the other hand of inconsiderable, diagnostic value. If the statement is correct, it should serve to stimulate us all to endeavour more often to see our patients during the presence of pain, and even in some instances to induce pain, by giving food or other means, in order that we may accomplish greater accuracy in diagnosis. As to the question of the existence and cause of actual visceral pain, Dr. Hurst's investigations and all clinical experience point to the conclusion that visceral sensation, including pain (whether gastric, intestinal, cardiac, renal, vesical, or elsewhere produced) is dependent on altered intravisceral tension, and that all visceral pain is relieved by lowering intravisceral tension.

I am, Sir, yours faithfully,

J. A. RYLE.

The Warden's House, Guy's Hospital, Feb. 5th, 1921.

To the Editor of THE LANCET.

SIR,—If, before instructing me in the elements of clinical methods, Dr. A. Murdoch had taken the trouble to read my Goulstonian lectures, which were published in THE LANCET in 1911—three years before he began to look for the viscero-motor and viscero-sensory reflexes—he would have found in them a full discussion of these symptoms, the importance of which I have constantly taught for the last 14 years. He would have realised that your references to my observations on Sir Berkeley Moynihan's patients with duodenal ulcer were only concerned with cutaneous hyperæsthesia, which is very rare indeed in cases of ulcer, in contrast with deep tenderness and rigidity, which are almost constantly present, especially at the height of an attack of pain. With regard to visceral pain the evidence I brought forward in 1911, and all my experience since, have convinced me that viscera themselves are sensitive, and that it is a matter of great clinical importance to distinguish between true visceral pain and tenderness on the one hand and reflex visceral pain and tenderness on the other.

I am, Sir, yours faithfully,

ARTHUR F. HURST.

Devonshire-street, W., Feb. 6th, 1921.

THE OPERATIVE TREATMENT OF PROLAPSE.

To the Editor of THE LANCET.

SIR,—I have been much interested in Mr. J. P. Lockhart-Mummery's communication to your pages of to-day on the Operative Treatment of Prolapse (Procidentia) of the Rectum in Adults, although, unlike him, I am not "convinced that it is far superior to any of the other methods" I have obtained results at least equal to those he mentions by the submucous injection of paraffin wax, as described by me in THE LANCET,[1] and since epitomised in successive editions of Jacobson's "Operations of Surgery," combined with a plastic operation for the restoration of the anal canal very similar to that detailed by Mr. Lockhart Mummery. This plastic operation is not necessary in every case, but is always carried out whenever the anus is patulous and the sphincter weakened—as obtains in most instances of long standing prolapse in adults. One of the most extensive cases I have treated is a lady upon whom, in 1906, at the age of 66, I performed this operation for an 8 inch prolapse associated with such extensive excoriation of the constantly prolapsed bowel as to confine her to bed; she is now, at the age of 81, able to get about actively and to strain, without any recurrence of the prolapse. Up to the present I have not heard of any case of failure after I have performed the combined procedure, nor have I had any serious complication afterwards. In comparison with Mr. Lockhart Mummery's operation I claim this method to be very much simpler and less severe, and to be associated with very much less discomfort in its after treatment The removal and replacement of the "as much as 40 yards of gauze" at the end of the first week in his method requires a second anæsthetic, and when this is again removed five days later, although it is not stated that anæsthesia is utilised, yet it must sometimes be wished for. The only special after treatment required in my method is the removal of the sutures used in the "plastic" portion of the procedure—practically painless.

The statement that "sepsis later is almost certain to occur . and is, in fact, desirable," is not altogether pleasant reading, moreover, it presupposes that the scar left after healing by "second intention" is more capable of withstanding subsequent pressure than that of "primary union," which I do not believe or I would deliberately court sepsis every time I perform a radical cure of hernia or close up a laparotomy wound. If I remember rightly, a generation or more ago such a course was actually advocated in the operation for hernia (McBurney), and, less remotely, has been practised as part of the operation for nephropexy, but I was unaware that the principle had received any wide recognition. On the contrary, if there be one fact more firmly established than another in relation to operations for hernia or for any other condition where the scar has subsequently to withstand pressure I should have thought it to be that sepsis, with its consequent healing by granulation, is the most important factor predisposing to a yielding of the scar.

Mr. Lockhart-Mummery writes: "In principle a prolapse is similar to a hernia and requires the same conditions for its cure," but in the next seven lines it becomes evident that he misses the whole point of the analogy, obviously regarding the prolapse of the rectum as the "stretching of some part of the contained viscera"—i e, as the equivalent of the *contents* of an ordinary hernia. This is not so. Prolapse of the rectum *is* a true hernia, of the pelvic floor, but the pelvic floor and rectum constitute the *coverings* and not the *contents* of the hernia, the analogue of the contents of the ordinary hernia is the omentum or small intestine which may occasionally occupy the prolongation of the pouch of Douglas, which accompanies, or rather *precedes* the descent of the rectum, which contents may, like the contents of other herniæ, become strangulated. The position of the rectum in relation to the hernia is exactly that of the cæcum or sigmoid colon in the so called "sliding" hernia, or "hernie par glissement"—i.e., it is extra-saccular. Further, I fail to discover any of the alleged similarity in principle between Mr. Lockart Mummery's operation and that for the radical cure of hernia. The *first*, and as many believe the *sole* essential of the latter, is a complete obliteration of the sac, which Mr. Lockhart Mummery does not even attempt. The only operation with which I am acquainted which really does act on this principle is that described by Dr. A. V. Moschowitz,[2] in which, through a laparotomy wound, the entire pouch of Douglas is obliterated by successive tiers of circular suture. I have performed this operation on three occasions with only partial success, having had to supplement it by a plastic restoration of the anal canal. Anyone who has attempted Moschowitz's procedure will agree that, owing to the surprising depth of the pouch of Douglas in these cases, it is a difficult and severe operation, and not in any way comparable to the easy and safe method of paraffin wax injection which I have described.

I am, Sir, yours faithfully

Manchester, Feb 5th, 1921 ARTHUR H. BURGESS.

PROPHYLAXIS IN VENEREAL DISEASE.

To the Editor of THE LANCET.

SIR,—I was pleased to read Mr. Kenneth M. Walker's letter in your last issue, suggesting that members of the two societies, the N.C.C.V.D. and the S.P.V.D., should arrange to meet. At an official interview with Sir Malcolm Morris last June I said I thought it was a pity that the two societies did not combine, as now their differences were those "twixt Tweedledum and Tweedledee." The N C C.V.D. considers that the recommendation of the washing with water and a well known chemical—namely, soap (which is potassium or sodium stearate, palmitate, or oleate, &c., or a combination of these according to the fats used in its preparation) is not encouraging vice, but that it is encouraging vice for the S.P.V.D. to recommend the use of less common, but scientifically proved to be very efficient, chemicals—namely, water and potassium permanganate, or a 33 per cent. calomel ointment. Also the S.P.V.D. recommends that as the latter are less common, they should be made more easily available. The N.C.C.V.D., however, recommends the use of these disinfectants at so called early treatment centres, which are really *delayed* disinfection centres In addition to the great cost of such centres there are grave reasons rendering their provision by sanitary authorities impracticable.[3]

Mr. Walker states that the N.C C.V.D. does not believe that the "packet" system would be effective when applied to the civil community. The S P.V.D., however, recommends a much less costly system—namely, education by means of posters and leaflets placed in men's underground conveniences, and the latter is the system that was adopted by the Holborn Borough Council last year. 50,000 of the leaflets are supplied at a cost of about £19, that is, less than 1*d*. for 10. For æsthetic reasons also a man is much more likely to adopt *self* disinfection than to go to a centre for disinfection by a skilled attendant. The S.P.V.D., while advocating that no moral measures should be neglected, recognises the plain unsavoury fact that a large proportion of the adult population (notwithstanding all these measures) has practised irregular sexual intercourse, and it therefore recommends the teaching of simple but efficient methods of self disinfection as a practical means of the prevention of venereal diseases; also that the prevention of disease by all practicable means is the paramount duty of sanitary authorities

The Holborn leaflet gives concise information—"What Every Man Should Know"—respecting the terrible ravages caused by these diseases; that the only safe, right, and manly course is to exercise self control; that prevention is infinitely better than cure; and that it is therefore the bounden duty of any man who will indulge in promiscuous sexual intercourse to adopt this disinfection in order to avoid disease, which he may pass on to innocent people. The poster has the same wording. On the back of the leaflet are simple directions respecting (1) immediate self-disinfection, (2) delayed self-disinfection, and the advice (3) if any symptoms of disease arise immediately to consult a doctor or attend one of the special clinics at a hospital. Posters respecting (3) are also exhibited.

---

[1] THE LANCET, 1901, ii, 759

[2] A paper read before the New York State Medical Society, April 16th, 1912, and published in Surgery, Gynæcology, and Obstetrics about that time

[3] A solution of potassium permanganate, 1 in 1000, is also well known as it was recommended by the Local Government Board and the Ministry of Health for the prevention of influenza.

Although any fairly intelligent youth or man can very easily carry out the simple directions, human machinery like other machinery is not fool-proof. Much venereal disease is the sequel of foolish indulgence in alcoholic beverages, and if a man will so render himself temporarily idiotic or imbecile he probably then would be unable to carry out efficiently direction (1), therefore the directions (2) and (3) are also given.

I am, Sir, yours faithfully,

Council Offices, High Holborn, Feb. 7th, 1921. W. A. BOND.

THE REGULATIONS FOR DANGEROUS DRUGS.

To the Editor of THE LANCET.

SIR,—I have been instructed by the Executive of the Portsmouth Division, B.M.A., to send to you the following resolution for insertion in THE LANCET:—

> "We, the members of the executive of the Portsmouth Division of the British Medical Association, having read the proposed regulations for the sale of dangerous drugs, &c., emphatically protest against their application to medical men, as it is utterly impossible to carry them out; the result will be, either that the practitioner will be bound to ignore the regulations, or his patients will be deprived of valuable and anodyne drugs, and thereby their sufferings will go unalleviated.".

It was further resolved that this resolution be sent to the Home Secretary, the local Members of Parliament, and the medical press.

I am, Sir, yours faithfully,
C. A. S. RIDOUT, F.R.C.S.,
Honorary Secretary, Portsmouth Division, B.M.A.
Southsea, Feb. 5th, 1921.

THE INDICATIONS FOR REMOVAL OF TONSILS.

To the Editor of THE LANCET.

SIR,—Most surgeons would agree with the conclusions arrived at by Mr. M. Vlasto in his interesting paper on tonsillectomy, which appeared in THE LANCET of Jan. 22nd; at the same time there are points made with which one may differ. He states that the dissection operation causes less *trauma to the faucial* pillars than the use of the guillotine. Following Dr. G. E. Waugh's paper in 1909 I made a practice of removing all tonsils in *children and adults* by the dissection method as a routine; about 1913 I learned of O'Malley's technique of enucleation by the reversed guillotine. I *have no hesitation* in stating my complete agreement with Dr. Dan McKenzie that "enucleation by the guillotine removes the whole of the tonsils yet spares the faucial pillars." My experience of both methods teaches me that the guillotine operation is much the better operation in the case of children, and will rarely fail to effect a complete enucleation if deliberately performed under good anæsthesia. There is no need for it to be a "messy" or "rushed" procedure if the coöperation of a skilled anæsthetist is obtained who is accustomed to work with the surgeon, and so controls the patient as to allow of deliberate swabbing and full inspection of the tonsillar beds. Although in hospital practice, owing to the large number of cases, the operation has perforce to be performed under ethyl chloride or gas and oxygen, these are not nearly so satisfactory as a chloroform and ether mixture. There is no operation in throat work in which a skilled anæsthetist can be of more assistance to the surgeon than in the one under consideration, by inducing the correct degree of anæsthesia, by the proper holding of the head, and by care of the mouth-gag.

In adults, on the other hand, I find that it is usually necessary to use the dissection method to effect complete enucleation, owing to the inflammatory adhesions about the capsule, but I regard this operation as much more formidable as regards risk of hæmorrhage and after-pain than the guillotine operations in children. I use the O'Malley guillotine and endeavour to follow the technique as described by him, and know of none safer or more satisfactory.

I am, Sir, yours faithfully,

Manchester, Feb. 7th, 1921. LINDLEY SEWELL.

THE HAND-MARKINGS OF MONGOLIAN IMBECILES.

To the Editor of THE LANCET.

SIR,—I shall be glad if you will allow me to insist, as I did in my recent paper read before the Medical Society of London, and reported in THE LANCET last week, that it was Dr. R. L. Langdon-Down, and not I, who originally described the peculiar hand-markings of Mongolian imbeciles. Dr. Langdon-Down's observation is one which has not merely clinical interest, but anthropological importance and theriomorphic significance. The latter is emphasised in Professor F. Wood Jones's recent work on the Hand, though the relation to "Mongolism" is not therein mentioned.

I am, Sir, yours faithfully,

Wimpole-street, W., Feb. 7th, 1921. F. G. CROOKSHANK.

THE INDUCTION OF ABORTION.

To the Editor of THE LANCET.

SIR,—The article by Sir John Phillips on this subject in THE LANCET of Feb. 5th opens up a question of great importance. My own experience leads me to believe that the necessity for the induction of abortion very rarely arises. Holding the offices successively of resident obstetric officer, house surgeon, and house physician at St. Mary's Hospital, and working under such well-known men as Alfred Meadows, Braxton Hicks, Montagu Handfield-Jones, Edmund Owen, and William Broadbent, I never once saw the operation performed, and during 30 years of private family practice I have never seen a case in which it was necessary.

Sir John Phillips enumerates a number of conditions under which he considers the operation justifiable or necessary, and I hope that others will comment upon his paper, so that some more definite ruling may be arrived at as to the circumstances under which the induction of abortion becomes a necessity. The operation is repugnant to the conscientious practitioner, and yet one has the feeling that it is sometimes lightly undertaken. That it is a proceeding fraught with very real danger to the patient, and far from easy to perform, there can be little doubt, and that it should never be undertaken without previous consultation, if possible with a gynæcological specialist, I venture to think should be an invariable rule.

I am, Sir, yours faithfully,

Sussex-gardens, W., Feb. 7th, 1921. E. M. CALLENDER.

PART-TIME OR WHOLE-TIME FOR THE M.O.H. AND S.M.O.

To the Editor of THE LANCET.

SIR,—The four writers in THE LANCET of last week upon my letter in the previous issue do not appear to have studied the report of the Consultative Council to which I have referred. Dr. I. D. Suttie, however, accepts in some degree the situation in the right light. Dr. G. W. Fleming, Dr. J. H. Gellatly, and Dr. T. Chetwood seem to be personally aggrieved and to be attempting to justify their positions. These three should most carefully study the report, when they must come to the only conclusion that is to be arrived at—viz., the present service of school medical officers is far from satisfactory. Otherwise, why are such radical changes advocated after 12 years? And this is the crux of the question.

I am, Sir, yours faithfully,

Chichester, Feb. 5th, 1921. A. M. BARFORD.

NITROUS OXIDE AND OXYGEN IN OBSTETRICS.

To the Editor of THE LANCET.

SIR,—Your annotation in THE LANCET of Jan. 15th with reference to the publication of the American Anæsthetic Research Association on the above subject is of interest, in that it emphasises the value attached in America to this method of rendering less painful the bearing of children. Native women, especially those of strong muscular development due to agricultural labour, can usually deliver themselves without much trouble; a Fijian once told me that for the women of her race it was "not much more exertion to bring a baby into the world than to defæcate." With us, unfortunately, labour is frequently pathological and pain is indeed real; its effects on the subsequent health of the mother may be as far-reaching as pain from any other source; hence "twilight sleep" and many other attempts directed towards its mitigation. As demonstrated in your article nitrous oxide analgesia has given satisfaction in the United States. It is popular there—and why not here also? I believe the accouchement position is the same in the two countries; gas can surely be given with absolute safety with the patient on her side in the knee-elbow position. The advantages claimed for nitrous oxide oxygen and nitrous oxide and air are that they permit the patient to bear down without pain or entire loss of consciousness; the gases either prevent painful stimuli from reaching the brain, or greatly reduce their intensity. Between the pains the patient is fully conscious and if desired can even walk about the room. The ideal method is, as you remark, for the administration to be done by an anæsthetist, using such an apparatus as the Teter, Gwathmey,[1] Geoffrey Marshall,[2] or the one described by the present writer.[3] For its portability and absence of fine adjustment valves the Marshall is without doubt the best, although a method of warming the gases would be an advantage.

The expense and difficulty of obtaining the services of an anæsthetist, perhaps for many hours, suggests the value of an apparatus, as used in America, with which the patient may administer the gases to herself, in the presence, of course, of the obstetrician. For this gas and air are the simplest means; what is necessary is enough nitrous oxide to control pain, together with sufficient oxygen or air to maintain adequate tissue respiration. About 10 per cent. to 15 per cent. air or 5 per cent. to 15 per cent. oxygen is needed, the amount varying with individual patients. Re-breathing warms the gases and is economical, but cannot, of course, be employed for self-administration. For this purpose a Colman gas valve is set so as to admit the minimum amount of air that will obviate cyanosis. With those who can and will facilitate nasal breathing a nose-piece may be employed, and pure nitrous oxide is then permissible; otherwise a Barth face-piece is used. When a pain comes on the woman places the mask over her face or adjusts the nose-piece, as the case may be; the handle of the apparatus, which will subsequently be described, is compressed; the patient breathes the gases and is eased of her pain when analgesia is established, but before the onset of anæsthesia she loses power to control the handle; the gases are automatically cut off, and readmitted when the handle is operated on return of pain.

The earlier pain of labour is certainly thus relieved, and exhaustion and shock prevented, without any danger to mother and baby. Complete deadening of pain may not always be obtained during the expulsion stage; for this, surgical anæsthesia with one of the apparatuses named, and the presence of an anæsthetist, are often required.

In designing a self-administration apparatus simplicity and precaution against any possible accident are the main considerations. If a gas-bag is employed the patient can cut off the gas-supply to herself, but not the supply to the bag; unless the obstetrician can turn the latter off at the cylinder the bag may burst and terrify the patient. To prevent this possibility a governor is fitted to the cylinder instead of a bag; when the patient releases the handle the gas is cut off at the source.

You have pointed out the desirability of some details of such an appliance, and I suggest that the latter need merely consist of a 200 gallon gas cylinder with a governor, tubing to connect the latter to the hand-piece, a nasal-piece, and a face-piece with a three-way valve. The hand-piece consists of a ⅛-inch brass tube, perforated at right angles by a double metal tube, the inner tube of which is attached to a handle and kept extended by a spring; the tubes are fitted with ports, so placed that unless the handle is compressed they are not in line and the gas cannot pass. About 100 gallons of gas should last fully over an hour; two or three cylinders should be enough for an average case. Grudel[4] reports cases in which it has been administered for ten hours.

I am, Sir, yours faithfully,
CHARLES T. W. HIRSCH,
Anæsthetist, Samaritan, National Dental Hospitals, &c.

MEDICAL PROVIDENT SCHEMES.

To the Editor of THE LANCET.

SIR,—In THE LANCET of to-day's date Mr. Charles A. Parker outlines a scheme for a Coöperative Polyclinic. Under this scheme a single man, with an income of £300, is to obtain his doctoring, medical and surgical, for an annual premium of £1 15s. No differentiation appears to be made between an earned income and an income derived from invested capital. An income of £300, if derived from investments, implies a capital of £6000.

Is it intended to supply the possessor of £6000 with medical and surgical treatment for a yearly premium of 35s.? If this is not the intention, what is there in the scheme, as outlined, to prevent such an occurrence?

I am, Sir, yours faithfully,
Plymouth, Feb. 5th, 1921. C. HAMILTON WHITEFORD.

LEAUCHOIL HOSPITAL, FORRES.—The annual general meeting of the governors of this hospital was held recently, Colonel Norman MacLeod, the chairman, presiding. The report showed that the funds on Dec. 31st, 1919, amounted to £17,749. During the year 1920 £1412 had been received, and after all expenditure had been met there was a balance at Dec. 31st, 1920, of £16,683 0s. 11d. The managers have realised part of their investments to meet the deficiency in the annual income.

Medical News.

UNIVERSITY OF SHEFFIELD.—The results of the December examinations in the Faculty of Medicine of this University are as follows:—

Diploma in Public Health.—W. J. Fordham, G. G. Marshall.
Third M.B., Ch.B.—Annie D. Sykes.

UNIVERSITY OF LONDON.—A lecture on the Innervation of Striped Muscle Fibres and Langley's Receptive Substance, will be given at the Royal Society of Medicine, 1, Wimpole-street, London, W., by Dr. J. Boeke, Professor of Embryology and Histology in the University of Utrecht, at 5 P.M., on Feb. 16th. Professor W. M. Bayliss, F.R.S., will preside at this lecture, which will be delivered in English, and will be addressed to advanced students of the University and to others interested in the subject. Admission is free, without ticket.—*University College:* A Chair of Embryology is to be founded at this College, to which an appointment will shortly be made at a salary of £1000. Dr. Charles Singer has been appointed to a Readership in the History of Medicine tenable at this College.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—An ordinary Comitia of the College was held on Feb. 3rd, Sir Norman Moore, the President, being in the chair.—Licences to practise physic were granted to 83 candidates who had conformed to the by-laws and regulations and passed the required examinations.—A letter was received from the secretary of the Voluntary Hospitals Committee, formed by the Ministry of Health to inquire into the financial position of the voluntary hospitals, inviting the College to send representatives to give evidence. A reply was sent, emphasising the importance of the voluntary principle in relation to the interests of the sick, medical education, and the advancement of medical knowledge. The President and Censor were nominated to represent the College if any information were desired on these points.—A report from the Committee of Management concerning the Conjoint Examination in Midwifery and Diseases of Women was received and discussed. It was referred back to the committee for further consideration and report.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—Arris and Gale lectures will be delivered as follows: The *Function of the Kidneys in Enlargement of the Prostate Gland*, by Mr. J. F. Dobson, M.S., on Friday, Feb. 18th, at 5 P.M.; the Azygos System of Veins in their Association with Surgical Affections, by Professor J. Howell Evans, M.Ch., on Monday, Feb. 21st, at 5 P.M.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—As the result of the Final Examination held from Jan. 11th to 28th, the following candidates were approved in the subjects indicated, but are not eligible for diplomas:—

Medicine.—Dulcie Stapleton Adkins, Royal Free; S. Almond, Manchester; G. Armitage, Leeds; H. K. Attacullagh, Royal Free; F. Back, St. Thomas's; E. T. Bailey, Middlesex; May Tilney Bassett, Sheffield; K. M. Bharucha, Bombay and London; R. W. Briggs, Cambridge and St. Thomas's; Marion Constance Vera Clarke, Royal Free; G. R. H. Cooper, Birmingham; P. G. Cumming, Manchester; Edith Margery Pearce Davies, Royal Free; J. R. Dow, Charing Cross; C. F. T. East, Oxford and King's Coll.; Kendwen St. Valentine Edwards, Univ. Coll.; A. Epstein, Birmingham; Olive Gwendolin Fisk, Cambridge and London; Janet Katherine Gatty, Univ. Coll.; Nellie Gray, Westminster; J. B. Gregor, Guy's; S. E. Harvey, St. Thomas's; W. E. Hayes, Oxford and St. Bart.'s; I. Hipshon, Leeds; J. Hollings, London; C. A. Horder, Cambridge and St. Bart.'s; R. W. P. Hosford, St. Bart.'s; Margaret Olwen Howell and M. Jaynkar, Univ. Coll.; B. L. Jeaffreson and L. M. Jennings, St. Bart.'s; J. G. L. Jones, Liverpool; E. J. L. Jones-Evans, St Thomas's; G. Kinneir, St. Bart.'s; Bessie Lovin, Univ. Coll.; C. G Lewis, Birmingham and Univ. Coll.; E. O. Lewis, Cambridge and Univ. Coll.; J. S. Lewis, St. Mary's; J. R. Lund, Cambridge and St. Thomas's; C. H. Macklin, Middlesex; D. McNair, Royal Free; S. E. J. Miedema, Amsterdam; J. C. R. Morgan, Westminster; L. S. Morgan, St. Bart.'s; B. S. Nisse, London; M. M Ostrowick, Edinburgh; W. A. Owen, London; R. J Parry, Univ. Coll.; Cassia Ethel Pratt, Royal Free; W. S. Ratnavale, Calcutta and London; L. M. Rice, Toronto; Edith Marjorie Rooke, Royal Free; T. S. Severs, Durham; L. Smalley, St. Thomas's; Y. A. Sumbul, St. Mary's; H. W. Taylor, Manchester; C. P. Thomas, Westminster; E. W. C. Thomas, St. Bart.'s; A. W. Tibbetts, Birmingham; J. C. Twomey, Liverpool; C. Verheyden, Edinburgh and Univ. Coll.; H. S. Ward, Leeds; L. K. Watson, Guy's; R. A. Webb, Johns Hopkins, Baltimore; and C. F. Young, London.

Midwifery.—Charlotte Katherine Jocelyn Almond, King's Coll.; S Almond, Manchester; G. Armitage, Leeds; F. Back, St. Thomas's; May Tilney Bassett, Sheffield and Charing Cross; F. Basham, Univ. Coll.; F. A. Bruning, King's Coll.; E. M. Burrell, Cambridge and St. Thomas's; H. S. Chadwick, Manchester; L. E. Claremont, Univ. Coll.; Marion Constance Vera Clarke, Royal Free; P. G. Cumming, Manchester; C. B. [illegible], King's Coll.; H. S. Davies, St. Thomas's; Muriel Alice Mary Davies, King's Coll. and St. George's; A. de Souza, Middlesex; S. Douglas and Kendwen St. Valentine Edwards, Univ. Coll.; A. H. El Ramli, Liverpool; J. C. Evans, London; L. Farris, Westminster; Emmie Dorothy Fenwick, St. Mary's; Olive Gwendolin Fisk, Cambridge and London; Betty Fletcher, Royal Free and St. Mary's; M. R. Flynn, Sydney; G. H. Froggatt, Sheffield; Katherine Mary Lovell Gamgee and A. J. Gardham, Univ. Coll.; J. E. Gaze and R. Goodman, Charing Cross; A. H. Hall, Birmingham and London; M. Hall and E. Hardy, Guy's; A. D. Hepburn, Westminster; R. J. Hodgkinson, Guy's; C. A. Horder, Cambridge and St Bart.'s; Margaret Olwen Howell, Univ. Coll.; D. J. Jones, Westminster; D. M. Jones, Univ. Coll.; Margaret Gray Jones, Royal Free; A. H. Kassem, Guy's; J. Kindness, Charing Cross; R. C. Lightwood, King's Coll.; C. G. Lingford, Middlesex; I. B. McCann, Guy's; J. F. C. McColl, Liverpool; A. G. Mackay, Edinburgh; D. McNair, Royal Free; Y. Maximos, Middlesex; Rose Moss, Charing Cross; B. S. Nisse, London; T. S. North, St. Mary's; H. A. Osborn, King's Coll.; R. E. Overton and R. J. Parry, Univ. Coll.; L. P. Phillips and F. A. Pickworth, Charing Cross; Marjorie Pierce and Cassia Ethel Pratt, Royal Free; P. R. Rashbrook, London; T. R. Rees, Cardiff and St. Bart.'s; L. M. Rice, Toronto; G. H. Roberts, Charing Cross; A. Robertson, Guy's; Edith Marjorie Rooke and Margaret Charlotte Scrace, Royal Free; J. Seelenfreund, London; H. Shannon, St. Bart.'s; Creina Shepherd, Calcutta and King's Coll.; A. E. Slater, Cambridge and St. Thomas's; H. K. Snell, King's Coll.; A. D. Soares, Bombay; Dorothy Mary Stewart, Royal Free and St. Mary's; A. E. Strawbaun, Guy's; B. H. Stribling, London; Lucy Maud Summerhayes, St. George's; H. R. J. Thomas and D. D. C. Thomson, London; A. W. Tibbetts, Birmingham; F. H. W. Tozer, London; C. Verheyden, Edinburgh and Univ. Coll.; H. S. Ward, Leeds; E. H. Weatherall, St. Bart.'s; L. R. A. Wells, Guy's; H. L. Willey, Cambridge and St. Thomas's; E. C. A. Wilson, Howard; and E. T. Wright, St. Mary's.

Surgery.—Dulcie Stapleton Adkins, Royal Free; F. G. L. Barnes, St. Bart.'s; E. C. Curwen, Cambridge and St. Thomas's; G. W. Elkington, Guy's; S. Farris, Cairo and Liverpool; A. J. Gardham, Univ. Coll.; Nellie Gray, Westminster; Marjorie Pearl Christine Greene, Royal Free; B. J. Hallowes, St. Bart.'s; C. B. Hawthorne, Cambridge and Birmingham; S. S. Hewitt, St. Mary's; R. W. P. Hosford and D. E. Jones, St. Bart.'s; J. T. Jones, Guy's; M. Kamil and R. Lee Michell, Middlesex; W. B. A. Lewis, Cambridge and St. Bart.'s; A. G. Mackay, Edinburgh; S. E. J. Miedema, Amsterdam; G. B. Oliva, Liverpool; F. A. Phillipps, Cambridge and St. Thomas's; K. P. Raman Pillay, Madras and London; J. G. Reed, St. Thomas's; A. M. Reid, Liverpool; J. Reith, Univ. Coll.; E. Savage, St. Bart.'s; H. E. Suter, St. Mary's; T. S. Severs, Durham; H. W. Taylor, Manchester; J. P. Traylen, London; W. J. G. Walker, Univ. Coll.; and L. S. Woolf, St. Mary's.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND.—Dr. T. Gillman Moorhead has been elected to the King's Professorship of Materia Medica in succession to Dr. W. G. Smith, who resigned last November.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH: PARKIN PRIZE.—The subject of the essay for the present period is, in terms of the deed: On the Effects of Volcanic Action in the Production of Epidemic Diseases in the Animal and in the Vegetable Creation, and in the Production of Hurricanes and Abnormal Atmospherical Vicissitudes. The prize, which is of the value of £100, is open to competitors of all nations. Essays intended for competition, written in English, should reach the secretary not later than Dec. 31st, 1921.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH, ROYAL COLLEGE OF SURGEONS OF EDINBURGH, AND ROYAL *FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.*—The following candidates have passed the Triple Qualification Examinations:—

THIRD EXAMINATION.

Herbert W. Amyes, Tarabai Kelarkar, Catherine Millar, Rachel Caplan, Irene Ward, Herman S. N. Menko, William Leo Murray, George H. Dobbin, Thomas John Muir, and Thomas T. Hoskins.

Pathology.—Charles W. de Villiero Pritchard and Albert Rudolf Rellum.

Materia Medica.—Ella Doris Messenger, Oliver H. D. Oliver, Akinlawon Adefolu, John Murray Cockburn, and Israel Rowstowsky.

FINAL EXAMINATION.

Richard Arthur Cooper, Frederick James Duncan Cass, Gabriel Jonas Downona Hammond, George John Murray, Jack Shulman, James Hugh Wilson, Arthur Cuthbertson, Mayberry Hugh Carleton, Henry Godfrey Fitz-Maurice, Alexander Forsyth Caddell, Parasuma Parthasarathy, Walter Granville Carew, Joseph Black, Alexander Tirumlaiya, Patabendi Martin Fernando, and John Bertram van Cuylenburg.

Medicine and Surgery.—Don James Hector Ferdinando.

Medicine and Midwifery.—Pauline Figdor, Reginald Edward Hopton, and John Bernard O'Neill.

Medicine.—Herbert Brown, Leo Hugo Peries, and Gwilym ap V. Jones.

Surgery.—John Murray.

Midwifery.—James Sydney Alex. Rogers and John Joseph M'Donald.

Medical Jurisprudence and Public Health.—W. A. M'K. Gibson, Peter J. H. Dobbin, C. T. Williams, Marguerite M. I. Swanson, J. B. Dyce, James Readdie, R. E. O'Keeffe, P. F. Malloch, Marjory J. A. Ogilvie, Alex. G. Thom, Arthur R. Lambie, Tarbai Kelarkar, Daniel R. Cilliers, J. A. H. Dykes, Edward James Sykes, and Thomas Francis Kelly.

HARVEIAN SOCIETY.—A meeting of this society *will be held at the Town Hall, Harrow-road, Paddington*, on Thursday, Feb. 17th, at 8.30 P.M., when a paper will be read by Dr. W. Brown on Psycho-analysis.

RONTGEN SOCIETY.—A general meeting of this society will be held on Feb. 17th, at 8.15 P.M., in the Physics Lecture Theatre, University College, Gower-street, London, W.C., when a paper on Intensifying Screens and Secondary Radiation will be read by Mr. N. E. Luboshey.

VERMIN REPRESSION SOCIETY.—A successful dinner was held at the Connaught Rooms, London, on Feb. 8th, Sir Bruce Bruce-Porter presiding. Various speakers called effective attention to the economic and hygienic losses arising from rats and other animal pests when left unchecked. The formation of official rat offices in every town was advocated.

SOCIETY OF SUPERINTENDENTS OF TUBERCULOSIS INSTITUTIONS.—A meeting of this society will be held at 122, Harley-street, London, W., on Feb. 14th, at 4 P.M., when the main business will be the consideration of reports by committees on the coördination of statistics, the training of nurses, and the standards of medical and nursing staffs in institutions for the treatment of tuberculosis.

MEDICO-PSYCHOLOGICAL ASSOCIATION OF GREAT BRITAIN AND IRELAND.—The next quarterly meeting of this association will take place on Feb. 24th, at 11, Chandos-street, Cavendish-square, London, W., at 2.45 P.M., Dr. W. F. Menzies in the chair. Sir Frederick Mott, F.R.S., in conjunction with Dr. Hayao, will read a paper on the Pathology of Dementia Præcox, especially in Relation to the Condition of the Ovaries.

NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS.—The Association is arranging for the International Union Against Tuberculosis (Paris) to be held in London from July 26th–28th. All countries which have joined the League of Nations, as well as the U.S.A., are represented on the Union, and delegates from about 25 different countries are expected to attend and to take part in the proceedings. Professor J. Calmette will open a discussion on the Modes of Diffusion of Tuberculosis Throughout the Races of the World, and three public addresses will be given by a Frenchman, an American, and an Englishman respectively. Visits to tuberculosis hospitals, sanatoriums, laboratories, and other institutions will be arranged.

OXFORD OPHTHALMOLOGICAL CONGRESS.—This Congress will assemble at Keble College, Oxford, on July 6th next, and the meeting will be held on July 7th and 8th. On the 7th a discussion on the Causes of Infection After Extraction of Senile Cataract will be opened by Dr. Victor Morax, of Paris. The Doyne memorial lecture will be delivered on the 8th by Mr. Ernest E. Maddox on Heterophoria. Members intending to take part in the discussion or desiring to contribute papers, pathological specimens, new *operations, and so forth, are* requested to send in their names as soon as possible to the honorary secretary, Mr. Bernard Cridland, at Salisbury House, Wolverhampton.

RETIREMENT OF PROFESSOR C. LLOYD MORGAN.—Professor Lloyd Morgan, formerly teacher in biology at the Bristol Medical School, is being entertained by the Association of Alumni of the University on Feb. 17th, on the occasion of his retirement from the professorship of psychology. The Chancellor of the university, Lord Haldane, will preside, and tickets (price 12*s.* 6*d.*) may be had on application to Mr. P. Haworth at the university. Although Professor Lloyd Morgan has not for some years now been teaching medical students he has retained an active interest in their work and welfare.

STUDENTS' MEDICAL SOCIETIES.—The following meetings are announced before the end of the winter session:—

St. George's Hospital Clinical Society.—The next meeting will be held on Feb. 17th, when Dr. R. Donaldson will read a paper on Influenza. On March 3rd, the last meeting, Dr. H. C. H. Bull will read a paper. All meetings are held at 8.30 P.M.

Guy's Hospital Pupils' Physical Society.—The next meeting will be on Feb. 17th, when demonstrations of pathological specimens and other communications will be given. On March 2nd there will be a clinical meeting, and on March 16th a paper will be read by Mr. C. H. Laver.

St. Thomas's Hospital Medical and Physical Society.—The next meeting will be held on Feb. 24th, when a paper on the Essentials of Success in Private Practice will be read by Sir Robert Fox-Symons. On March 10th Sir Archibald Reid will speak on Opaque Meals in the Diagnosis of Abdominal Disease. The meetings are held at 8.30 P.M.

ENCEPHALITIS LETHARGICA.—Twenty-nine cases *were notified in London during the week ending Jan. 29th.* Of these 5 occurred in Lambeth, 4 in Hackney, and 4 in Lewisham. The other cases notified were from Woolwich (3), Wandsworth and Shoreditch (2 each), and Battersea, Bethnal Green, Bermondsey, Camberwell, Finsbury, Hampstead, Poplar, Stepney, and Southwark (1 each).

PRESENTATIONS TO MEDICAL MEN.—On his retirement from the office of Principal of Grant Medical College, Bombay, Lieutenant-Colonel Ashton Smith was presented with a farewell address by past and present students at a representative gathering presided over by Major-General W. E. Jennings, K.H.P., Surgeon-General to the Government of Bombay. At the same meeting a portrait was unveiled of General Jennings, which has been presented to the College by his numerous admirers. General Jennings has served in Bombay for nearly all his service, and has taken a very prominent part in the public life of the city.—On his appointment as consulting physician to the National Hospital for Diseases of the Heart, to which hospital he has been a physician for 23 years, Dr. C. Chapman Gibbes was presented by his colleagues on the staff with a silver salver as a token of appreciation. The out-patients also presented him with a silver salver, with a letter expressing great regret at his retirement, and a further presentation has been made to Mrs. Chapman Gibbes of a handsome bowl and stand.—Dr. G. S. Trail, who has recently retired from practice after 43 years' service in Strichen, was on Jan. 19th given a silver salver suitably inscribed and a cheque for £130 by 493 friends and neighbours in the local town hall.

CONGRESS OF RADIOLOGY AND PHYSIOTHERAPY.—A Congress organised by the Electro-Therapeutic Section of the Royal Society of Medicine and the British Association of Radiology and Physiotherapy will be held this year in London on April 14th, 15th, and 16th. The President will be Sir Humphry Rolleston, supported by a long and distinguished list of *Vice-Presidents. The secretary-general is* Dr. G. Harrison Orton; the honorary secretaries for General Correspondence are Dr. Stanley Melville and Dr. Justina Wilson; and the honorary secretaries for Sections are Radiology, Dr. N. S. Finzi; Electrology, Dr. G. Murray Levick; and Physiotherapy, Dr. C. V. MacKay. The provisional programme is as follows: On April 14th, at 10 A.M., the congress will be opened at the Royal Society of Medicine. At 11 A.M. the Section of Radiology will discuss Diseases of Bone; the Section of Electrology, the Action of the Direct (constant) Current on the Tissues in Health and Disease; and to the Section of Physiotherapy, addresses on Physical Training and on the Chartered Society of Massage and Medical Gymnastics will be given. In the afternoon the Section of Radiology will meet at St. Bartholomew's Hospital, where papers and a demonstration on the Intra-peritoneal Injection of Oxygen will be given, and the radiographic departments of selected hospitals will be visited. Members of the Section of Electrology will visit the electrical departments of selected hospitals, while the Section of Physiotherapy will discuss the Treatment of Cardiac Disorders by Physical Means. In the morning of Friday, April 15th, the Section of Radiology will discuss the Normal Stomach; the Section of Electrology, the Uses of Electrical Methods in the Diagnosis and Prognosis of Paralysis; and the Section of Physiotherapy, Physical Treatment as an Aid to Orthopædic Surgery. In the afternoon the Section of Radiology will proceed to the consideration of the Abnormal Stomach, while the other two sections will hold a joint meeting to discuss Re-education of Muscles. On Saturday, April 16th, the Section of Radiology will discuss Deep Therapy and Radium Therapy; the Section of Electrology will deal with the subject of the Physiological Action and Therapeutic Uses of High-frequency Currents; and the Section of Physiotherapy with Backache and Referred Pain. Those who have already promised to contribute the opening papers at certain of the sessions include Dr. S. G. Scott, Dr. Wybauw, Dr. A. E. Barclay, Dr. Kouindjy, Dr. Finzi, and Dr. J. E. A. Lynham. It is hoped that in each section there will be three opening papers in each subject—one from France, one from Belgium, and one from England, each limited to 20 minutes, and followed by a discussion, limited to 10 minutes for each speaker. All communications may be made in French or English. A résumé of all opening papers should reach the secretaries not later than three weeks before the opening of the Congress, and should be addressed to the Royal Society of Medicine. Associated with the Congress will be an exhibition of X ray and electrical apparatus, and a demonstration of physical training, organised by the Ling Association, at the Royal Albert Hall on Saturday, April 16th, at 2.30 P.M. The subscription for English members is £2 2*s.*, for French and Belgian members Fr.40. Application for membership should be sent with the subscription to the honorary treasurer, Dr. J. Metcalfe, Royal Society of Medicine, 1, Wimpole-street, London, W. 1, as early as possible.

Colonel S. Lyle Cummins has vacated the post of professor of pathology at the Royal Army Medical College, London, and has assumed duty as Professor of Tuberculosis at University College, Cardiff.

LONDON HOSPITAL MEDICAL COLLEGE (UNIVERSITY OF LONDON).—A course of 12 lecture-demonstrations on Gonorrhœa will be given by Mr. E. R. T. Clarkson and Mr. Malcolm Simpson (chief assistants to the genito-urinary department of the hospital) on Tuesdays, Wednesdays, Thursdays, and Fridays, at 4.30 P.M., in the venereal out-patient department, beginning Tuesday, March 1st. Members of the medical profession are invited to attend.

MIDDLESEX HOSPITAL MEDICAL SCHOOL (UNIVERSITY OF LONDON).—Two Emeritus lectures will be delivered in the new theatre of the school on Tuesday, Feb. 22nd, and Friday, Feb. 25th, at 3 P.M. On Tuesday Sir Alfred Pearce Gould takes as his subject "Surgery: a Progressive Science—the Latest Word is Not the Last Word." On Friday Sir Richard Douglas Powell will lecture on "The Ætiology of Phthisis." Visitors are cordially invited.

MANCHESTER'S ANTIVENEREAL POSTER.—Reference has already been made in THE LANCET (1920, ii., 813) to a poster on prevention of venereal diseases affixed in the public lavatories in Manchester. This poster was withdrawn and a new poster which the health committee proposed to issue was considered at a meeting of the city council held on Feb. 2nd, with the result that certain clauses therein were ordered to be deleted by a majority of 4 to 1. Strong objection was taken to certain clauses not only in the council but also by certain outside bodies. One of those complained of read: "Men who are determined to disregard their moral obligations should read the leaflet, 'Directions to Men,' which may be obtained by men on personal application to the Medical Officer of Health, 1, Mount-street, Manchester." The other clauses indicated the position of the centres for early treatment and emphasised the necessity of early action.

ALL-INDIA MEDICAL CONFERENCE.—The fourth session of the All-India Medical Conference was recently held, under the presidency of Dr. Maharaj Krishna Kapur, of Lahore. Over 100 delegates, representing all grades of the profession, attended. The chairman of the reception committee laid stress on the necessity for a reorganisation of the medical services in India and an improvement in medical education. He dwelt on the want of medical relief in the country districts, and expressed the hope that sanitation and medical aid would receive more attention from Government in the future than has hitherto been the case. The President in his address urged the need for better facilities for medical research and for post-graduate training. He emphasised the need for separating the military and civil medical services and the establishment of more hospitals and medical institutions.

DONATIONS AND BEQUESTS.—Messrs. George and Henry Wills have contributed a further £200,000 to finish the building extension of the University of Bristol, which is being erected entirely at their expense.—The Chelsea Hospital for Women has received towards the building of its Nurses' Home £100 from the executors of the late Mr. F. L. Harvey, also £25 from the trustees of the late Robert Williams Edwards Trust.—Under the will of the late Mr. William Morrice Ledingham, of Aberdeen, who died on Sept. 22nd last, leaving £186,000, the sum of between £80,000 and £100,000 will be divided into 17 shares, charitable institutions benefiting in the following proportions: Aberdeen Royal Infirmary, 4 shares; Royal Aberdeen Hospital for Sick Children, 2; Aberdeen District Nursing Association, 1; Newhills Convalescent Home, 1; Aberdeen Asylum for the Blind, 1; Aberdeen Ophthalmic Institute, 1; Aberdeen Dispensary, Maternity Hospital, and Vaccine Institute, 1; Morningfield Hospital, 1.—In aid of Sir James Taggart's Sick Children's Hospital Scheme the employees of Messrs. Mitchell and Rae, Newburgh and Ellon, have contributed four hours' wages, amounting to £58, and the firm have added another £58, making £116 altogether. The Aberdeen city tramwaymen have decided to contribute in the same proportion, and it is hoped that £100 may be obtained from this source. Up to date the town council departments have contributed nearly £210 towards the scheme. The gas-workers have agreed to contribute 1s. each weekly for six weeks.—By the will of the late Mr. W. R. Teage, of Devon and London, the testator, after bequeathing some £75,000 of his estate, which amounts to £80,757 gross value with net personalty of £78,457, to his family and others, bequeathed the residue of his property as follows: Ten-fortieths to the South Devon and East Cornwall Hospital, Plymouth; four-fortieths each to Dartmouth Cottage Hospital and King Edward's Hospital Fund; two-fortieths each to Guy's Hospital, London Hospital, Poplar Hospital, Royal National [illegible] Boat Institution, Boys' Home Industrial School, and [illegible] Market Army Training School for Boys; one-fortieth each to the Middlesex Hospital, the Cancer Investigation Department of the Middlesex Hospital, Royal London Ophthalmic Hospital, Devon and Cornwall Homœopathic Hospital, Devon and Cornwall Ear and Throat Hospital, Plymouth Eye Infirmary, Home for the Dying Poor, Pembridge-square, W., London City Mission, Fox Court Ragged School Mission, and the Charity Organisation Society.—Under the will of the late Mr. H. Ainsworth, of Johannesburg, £1000 are bequeathed to Dr. Barnardo's Homes, and £1000 to the feoffees of Cheetham Hospital, Manchester.—Dr. David Lloyd Roberts, of Manchester, who died on Sept. 27th, 1920, aged 86, has left a fortune of £125,677, the net personalty being £104,462. The chief bequests are £5000 to the Royal Society of Medicine; £5000 to St. Mary's Hospital, Manchester; £3000 to the Manchester Royal Infirmary; £3000 to the Royal College of Physicians, London; £3000 to the Medical Society of London; an additional £500 each to the above societies for an annual lecture on any subject of medical or scientific interest; £2000 to St. David's College, Lampeter; £2000 to the Board of Finance of the Diocese of Manchester in trust for St. David's Church in Lyne-road, Chorlton-on-Medlock. His mezzotints and his water colours, which are mainly of the early English school, ancient glass, and antique silver are left to the Corporation of Manchester for the Art Gallery. After certain other legacies have been deducted, the residue, about £70,000, is to go to University College at Bangor for general purposes.

Appointments.

MACKENZIE, E. A., M.B., Ch.B., D.P.H., has been appointed Assistant Tuberculosis Physician to the King Edward VII. Welsh National Memorial Association.

STUART, F. J., M.R.C.S. Eng.; Medical Superintendent of the County Mental Hospital, Berry Wood, Northampton.

Wolverhampton and Staffordshire General Hospital.—Hon. Specialist.

THE Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at King's Cliffe, at Slamannan, and at Monmouth.

Births, Marriages, and Deaths.

BIRTHS.

CARNEGIE DICKSON.—On Jan. 31st, at Devonshire-street, W., the wife of W. E. Carnegie Dickson, M.D., F.R.C.P.E., Brunswick-place, Regent's Park, N.W., of a daughter.

DICKSON.—On Feb. 4th, the wife of Ian D. Dickson, M.D., Thorpe-road, Norwich, of a daughter.

EAGER.—On Feb. 6th, at Exminster, Devon, the wife of Richard Eager, O.B.E., M.D., of a son.

HALL.—On Jan. 9th, 1921, at 6, Dunluce Terrace, Belfast, the wife of Dr. Robin Hall, of a daughter.

LEE.—On Jan. 30th, at Cardigan-road, Headingley, Leeds, the wife of Harry Lee, F.R.C.S., of a daughter.

MARRIAGES.

HAVARD—HUMPHREY.—On Feb. 5th, at the Chapel Royal, Savoy, Arthur William Havard, M.B., B.S. Lond., late R.A.M.C., to Ursula Vernon, eldest daughter of Major and Mrs Vernon Humphrey, of Ridgmount-gardens, W.

NICHOL—WEIR.—On Jan. 18th, at Caledonian Hotel, Edinburgh, John MacRae Sandilands Nichol, M.B., Ch.B. Edin., to Dorothy, only daughter of Mr. and Mrs. John B. Weir, of 4, Salisbury-road, Edinburgh.

PAULIN—MILLIGAN.—On Feb. 2nd, at St. Paul's Church, Bedford, Dr. George Alexander Paulin, to Mary, daughter of the late Dr. and Mrs. Milligan, De Parys-avenue, Bedford, and Cranfield, Bedfordshire.

DEATHS.

FOSTER.—On Feb. 4th, at the Abbey, Thorpe-le-Soken, Essex, Dr. Francis Wheldale Foster, aged 61.

HARRIS.—On Feb. 5th, at Queen's-road, Southport, Robert Harris, M.B., J.P., aged 73 years.

MILNE.—On Feb. 3rd, at Nordrach-on-Dee, George Wardlaw Milne (late Lieutenant-Colonel, R.A.M.C., T.C.), aged 47.

SCOTT.—At "The Tower," Murrayfield, Edinburgh, on Feb. 2nd, Sarah Jeffrey, wife of Dr. Joseph Scott, Teheran, Persia.

STAPLE.—On Feb. 4th, at Lyme Regis, James Dibble Staple, M.R.C.S., L.S.A., formerly of Cheltenham-road, Bristol, in his 60th year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, Feb. 15th.

GENERAL MEETING OF FELLOWS: at 5 P.M.
Ballot for Election to the Fellowship. (Names already circulated.)

MEETINGS OF SECTIONS.

Monday, Feb. 14th.

WAR SECTION: at 5 P.M.
Exhibition and Demonstration of Splints and Similar Apparatus by Major Meurice Sinclair.
At 9 P.M.:
Major Meurice Sinclair will read a paper (with illustrative slides).

SECTION OF SURGERY: SUBSECTION OF ORTHOPÆDICS: Members of this Section and Subsection are cordially invited to attend the above meeting.

Tuesday, Feb. 15th.

SECTION OF THERAPEUTICS AND PHARMACOLOGY: at 4.30 P.M.
Papers:
Dr. J. H. Burn: Comparison of Digitalis Tinctures by Different Physiological Methods.
Dr. P. Hamill: Oral Administration of Pituitary Extract (Experimental).
Dr. Donaldson: Oral Administration of Pituitary Extract (Clinical).

SECTION OF PATHOLOGY: at 8.30 P.M.
Communications, &c.:
Dr. W. E. Gye and Dr. E. H. Kettle: Passive Immunity in Tetanus.
Dr. Mackenzie Wallis: Demonstration on Estimation of Sugar in the Blood.
Dr. A. E. Gow: A Specimen of Pancreatic Infarct and Fat Necrosis.
Dr. T. H. G. Shore: (1) Influenzal Meningitis of Spinal Cord; (2) Knee-joint in Hæmophilia; (3) Retrograde Metastases in Carcinoma.
Dr. E. H. Kettle: (1) A Congenital Sacral Teratoma; (2) A Primary Chancre of a Finger following Trauma.

Members desiring to read papers or show specimens are requested to communicate with Dr. E. H. Kettle, 35, Nottingham-place, W. 1.

Wednesday, Feb. 16th.

SECTION OF HISTORY OF MEDICINE: at 5 P.M.
Mr. Robert Steele: The Introduction of Astrology into Western Medicine (Preliminary).
Sir D'Arcy Power: Some XVII. Century Statistical Tables of St. Bartholomew's and St. Thomas's Hospitals.
Dr. Haldin Davis: A Very Early Illustration of a Skin Disease.

Thursday, Feb. 17th.

SECTION OF DERMATOLOGY: at 5 P.M. (Cases at 4.30 P.M.)
Cases: The following will be shown by—
Dr. H. MacCormac: Darier's Disease (?).
Dr. J. L. Bunch: Boeck's Sarcoid.
Other cases will be shown.

Friday, Feb. 18th.

SECTION OF OTOLOGY: at 5 P.M. (Cases at 4.45 P.M.)
Paper:
Dr. A. R. Friel: Zinc Ionisation and Electrolysis in the Treatment of Chronic Otorrhœa.
Cases will be shown by—
Mr. Mollison, Dr. Hutchison, Mr. Cleminson, and Mr. Norman Patterson.

SECTION OF ELECTRO-THERAPEUTICS: at 8.30 P.M.
Social Evening:
Members are invited to communicate with the Hon. Secretary (Dr. Melville, 9, *Chandos-street*) if they wish to show skiagrams of unusual affections of bone, or to bring such for diagnosis.

There will be an informal discussion on questions of interest affecting the Section.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.
MONDAY, Feb. 14th.—8.30 P.M., Discussion on Skin Disease, its Relation to Internal Disorder, opened by Sir James Galloway. Followed by Dr. A. Hall, Dr E. W. Goodall, Dr. A. Whitfield, Dr. E. G. Little, Dr. H. W. Barber, Dr. H. G. Adamson, Dr. J. M. H. McLeod, Dr. H. MacCormac, Dr. R. Hutchinson.

LONDON DERMATOLOGICAL SOCIETY, St. John's Hospital, 49, Leicester-square, W.C.
TUESDAY, Feb. 15th.—4.30 P.M., Pathological Specimens. Cases sent for Consultation. Clinical Cases will be shown by Dr. J. L. Bunch, Dr. W. Griffith, Dr. E. J. D. Mitchell, Dr. S. R. Kapoor, Dr. W. K. Sibley, Dr. Eva White.

HUNTERIAN SOCIETY, at Sion College, Embankment, E.C.
WEDNESDAY, Feb. 16th.—9 P.M., Annual Oration:—Dr. H. H. Bashford: The Ideal Element in Medicine.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 11, Chandos-street, Cavendish-square, W.
FRIDAY, Feb 18th.—7.45 P.M., Microscopic Specimens. 8.15 P.M., Papers:—Lt.-Col. J. O. Kennedy, R.A.M.C.: Some Observations on the Pathology of Relapsing Fever.—Dr. A. M. Cole: Five Cases of Sasciolopsis Infection, with Remarks.—Dr. A. Connall: Results of the Examination of Chrysops for Filaria in West Africa.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.

MONDAY, Feb. 14th.—4 P.M., Hunterian Oration: Sir Charters J. Symonds.

WEDNESDAY.—5 P.M., Arris and Gale Lecture:—Dr. F. W. Edridge-Green: The Cause and Prevention of Myopia.

FRIDAY.—5 P.M., Arris and Gale Lecture:—Mr. J. F. Dobson: *The Function of the Kidneys in Enlargement of the Prostate Gland.*

UNIVERSITY OF LONDON, at the Rooms of the Royal Society of Medicine, 1, Wimpole-street, W.

Advanced Lecture in Medicine to Students of the University and others interested in the subject.

WEDNESDAY, Feb. 16th.—5 P.M., Dr. J. Boeke: The Innervation *of Striped Muscle Fibres and Langley's Receptive Substance.*

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Feb. 14th.—2 P.M., Dr. Simson: Diseases of Women. 2.30 P.M., Mr. Baldwin: Visit to Surgical Wards. Dr. A. Saunders: Demonstration of Medical Cases (Medical Wards). 5 P.M., Lecture:—Mr. B. Harman: Intestinal Sepsis and Irido-cyclitis.

TUESDAY.—12 noon, Mr. T. Gray: Demonstration of Fractures. 2 P.M., Dr. Burnford: Medical Out-patients. 2.30 P.M., Mr. Addison: Visit to Surgical Wards. 5 P.M., Lecture:—Dr. Morton: X Ray Appearances of Some Diseases of the Stomach.

WEDNESDAY.—10 A.M., Mr. MacDonald: Genito-Urinary Department. 2 P.M., Mr. Gibb: Eye Department. Mr. D. Armour: Demonstration of Surgical Cases (Surgical Wards). 5 P.M., Lecture:—Dr. Owen: Some Principles of Treatment in *Gastric Disorders.*

THURSDAY.—2 P.M., Dr. S. Pinchin: Medical Out-patients. Mr. D. Armour: Operations. Mr. Baldwin: Orthopædic Department. 5 P.M., Special Lecture:—Dr. I. Bruce: X Ray Diagnosis of Diseases of Joints (open to all medical practitioners).

FRIDAY.—10 A.M., Dr. McDougal: Electrical Department. 2 P.M., Mr. Banks Davis: Diseases of the Throat, Nose, and Ear. Dr. Pernet: Skin Department. 5 P.M., Lecture:—Mr. Baldwin: Appendicitis.

SATURDAY.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 12 noon, Mr. Sinclair: Surgical Diseases of the Abdomen. 2 P.M., Dr. Owen. Medical Out-patients.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Feb. 14th.—10 A.M., Mr. W. E. Tanner: Surgical Out-patients. 2 P.M., Dr. A. J. Whiting: Medical In-patients. 2.30 P.M., Mr. E. Gillespie: *Surgical Operations.* Mr. J. B. Banister: Gynæcological Out-patients. Dr. J. B. Alexander: Medical Out-patients. 4.30 P.M., Clinical Demonstration:—Mr. W. E. Tanner: Selected Surgical Cases. 6 P.M., Dr. F. L. Provis and Mr. T. H. C. Benians: Venereal Department.

TUESDAY.—9.45 A.M., Lieut.-Col. R. H. Elliot and Mr. N. Fleming: Eye Operations. 2.30 P.M., Mr. H. W. Carson: Surgical Operations. Mr. C. H. Hayton: Diseases of the Throat, Nose, and Ear. Dr. Metcalfe: X Ray Department. 4.30 P.M., Clinical Demonstration:—Dr. A. J. Whiting: Innocent Irregularities of the Heart. 5.30 P.M., Dr. C. E. Sundell: Children In-patients.

WEDNESDAY.—2 P.M., Mr. C. H. Hayton: Throat Operations. 2.30 P.M., Dr. W. J. Oliver: Skin Department. Dr. J. B. Alexander: Medical Out-patients. 3 P.M., Clinical Demonstration:—Dr. W. J. Oliver: Cases of Skin Disease. 5 P.M., Dr. Provis and Mr. Benians: Venereal Department.

THURSDAY.—2.30 P.M., Mr. N. Fleming: Eye Out-patients. Dr. A. J. Whiting: Medical Out-patients. Mr. H. W. Carson: Surgical Out-patients. Mr. J. B. Banister: Gynæcological Operations. Dr. J. Metcalfe: X Ray Department. 3 P.M., Clinical Demonstration:—Mr. H. W. Carson: Selected Surgical Cases.

FRIDAY.—2 P.M., Mr. Howell Evans: Surgical Operations. 2.30 P.M., Dr. C. E. Sundell: Children Out-patients. Mr. E. Gillespie: Surgical Out-patients. 3 P.M., Clinical Demonstration:—Mr. T. H. C. Benians: Diagnostic Methods of Clinical Pathology. 5 P.M., Dr. Provis and Mr. Benians: Venereal Department.

SATURDAY.—3 P.M., Mr. H. W. Carson: Surgical In-patients.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, W.C. 1.

MEDICAL SCHOOL.

MONDAY, Feb. 14th.—2 P.M., Out-patient Clinic: Dr. Collier. 3.30 P.M., Lecture:—Dr. Kinnier Wilson: Old and New Afferent Systems.

TUESDAY, Feb. 15th.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Lecture:—Dr. Collier: Acute Polyneuritis.

THURSDAY, Feb. 17th.—2 P.M., Out-patient Clinic: Dr. Farquhar Buzzard. 3.30 P.M., Dr. Taylor. Lecture Room. Demonstra*tion of Cases.*

FRIDAY, Feb. 18th.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Dr. Tooth. Lecture Room. Demonstration of Cases.

Fee for Post-Graduate Course £7 7*s.* C. M. HINDS HOWELL, Dean.

KING'S COLLEGE (DEPARTMENT OF SCIENCE), Strand.

Nine Lectures on Problems of Modern Science.

WEDNESDAY, Feb. 16th.—5.15 P.M., Lecture (V.):—Prof. W. T. Gordon: Geology.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Feb. 17th.—4 P.M., Lecture:—Dr. Cockayne: Myopathy.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westmoreland-street, W.

MONDAY, Feb. 14th.—5.30 P.M., Post-Graduate Lecture:—Dr. R. Wells: Irregular Heart Action.

ST. MARYLEBONE GENERAL DISPENSARY, 77, Welbeck-street, Cavendish-square, W.

Post-Graduate Course on Infant and Child Welfare.

TUESDAY, Feb. 15th.—10.30 A.M., Dr. E. Pritchard: Practical Demonstrations on the Management and Feeding of Infants and Young Children—Demonstration IX., Treatment of Minor Ailments.

THURSDAY.—3 P.M., Demonstration X., The Training of the *Motor Functions of the Digestive System.*

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

TUESDAY, Feb. 15th.—4.30 P.M., Lecture:—Dr. F. E. Tylecote: Lumbar Puncture and its Value in Diagnosis.

SALFORD ROYAL HOSPITAL AND ANCOATS HOSPITAL POST-GRADUATE DEMONSTRATIONS, at the two Hospitals alternately.

THURSDAY, Feb. 17th.—4.30 P.M., Mr. Smalley: Importance of Early Recognition and Treatment of Nasal Sinusitis. (At Salford Royal Hospital.)

ST. MARY'S HOSPITALS, MANCHESTER, POST-GRADUATE LECTURE, at Whitworth-street West Branch.

FRIDAY, Feb. 18th.—4.30 P.M., Mr. Morley: Acute Intestinal Obstruction in Infants.

MANCHESTER BABIES' HOSPITAL.

Post-Graduate Lectures and Demonstrations in the Onward Buildings, Deansgate, or at the Hospital, Slade-lane.

SATURDAY, Feb. 19th.—3.30 P.M., Dr. Renshaw: Congenital Syphilis. (At Onward Buildings.)

MANCHESTER FRENCH HOSPITAL POST-GRADUATE LECTURES, 24, Acomb-street, Whitworth Park.

THURSDAY, Feb. 17th.—4.30 P.M., Dr. N. C. Haring: Some Chronic Lung Diseases.

Notes, Short Comments, and Answers to Correspondents.

THE WORK OF THE METROPOLITAN ASYLUMS BOARD FOR THE MENTALLY DEFECTIVE.[1]

BY THE VERY REV. CANON SPRANKLING,
CHAIRMAN, METROPOLITAN ASYLUMS BOARD.

THE Metropolitan Asylums Board were required by an Order of the Local Government Board dated April 2nd, 1897, to provide accommodation for Poor-law children "who by reason of defect of intellect...... cannot properly be trained in association with children in ordinary schools." It is of some historical interest to trace briefly the steps taken by the Board to deal with these children.

The Children's Committee (the Central Committee appointed by the Board to deal with cases under the Order of 1897) decided that it would be well to proceed experimentally by providing accommodation in ordinary dwelling houses scattered over the London area, each in touch with one of the special schools provided by the London County Council; at one time there were actually five such homes in existence, the first having been opened in January, 1899. The object was to provide the children with something as nearly akin as possible to the home life of a normal London child, and a house-mother was appointed for each home. The children attended the local special schools, and in some cases considerable improvement was effected. In 1906 provision was found necessary for continuance of control over the children after they reached the age of 16. The Bridge Training Home at Witham in Essex was opened as a working colony for male patients, while High Wood School, Brentwood, which is an institution built on the cottage home principle, had one of the groups of cottages, containing 60 beds, allocated for the accommodation of the elder feeble-minded girls. In 1911, however, the Board referred the whole question of systematic reclassification and treatment of the mentally defective cases, which fell within their sphere of work, to a special committee, who came to the conclusion that the experiment now under discussion had, in spite of all efforts, met with little success. The Committee formed the view that the permanent retention of the majority of the feeble-minded children was necessary in the interests of themselves and of the community, and that by this very fact the desired results could be obtained with as great efficiency in large colonies as in small scattered homes, and much more economically. Recommendations were submitted which led to the placing of all mentally defective persons in the Board's institutions, including the children already referred to (who were not certified under the Lunacy Acts) under the care of the Board's Asylums Committee.

Provision of Certified Accommodation for the Mentally Defective.

The passing of the Mental Deficiency Act, 1913, as it did not place on the Board any duties in regard to the provision of accommodation for mental defectives, did not immediately alter the policy which had been pursued in the past. In May, 1914, however, the Board were approached by the local authority for the metropolis (the London County Council) with a view to their providing certified accommodation under Section 37 of the Act for certain classes of the mentally defective. While the matter was under consideration war broke out; the situation became so altered that the Board felt themselves unable to enter into an agreement such as was suggested. Two years later, however, an opportunity arose for the resumption of negotiations at the instance of the Board of Control and of the London County Council. Ultimately it was arranged that five of the Board's institutions should be certified for the treatment of cases under the Act of 1913, the whole to form a group known as the Metropolitan Asylums Board Certified Institution. Darenth Training Colony and Bridge Training Home were to receive improvable juveniles, Leavesden and Caterham Mental Hospitals were to receive unimprovable adults from 16 years and upwards, and the Fountain Mental Hospital to receive idiot children. The Board made it perfectly clear that they could only undertake this work on special conditions. For instance, it was essential that they should have the absolute right to accept or reject any cases so that in no way should their normal work be jeopardised, and that, further, owing to the existence in their institutions side by side of two classes of certified cases, it would be impossible to follow all the prescribed forms required under the regulations laid down by the Board of Control. There were other stipulations such as a provision that patients might be transferred by the Board from one section of the certified institution to another without the consent of the Board of Control, and also that patients should be treated in precisely the same way as the Poor-law cases received under the Lunacy Acts. The general idea was that the Board might be able to accept something up to 500 mental defectives from the London County Council area and from the Home Counties, with perhaps a few from provincial areas. In 1918, all arrangements having been made, the first cases were admitted.

To-day the Board have about 1000 mental defectives under their care, having thus exceeded by 100 per cent. the utmost promise they were able to hold out in 1917, but the available accommodation and the demand for it are now more or less equalised. Circumstances have rendered it necessary or desirable to depart in a measure from the original arrangements as to the classes of cases to be received at the different institutions. So far as Darenth is concerned, there has been, indeed, no change whatever, cases sent there being all of the trainable class, but it has been found that there are a goodly number of lower-grade cases who, while not prima facie likely to benefit by the special form of instruction given at Darenth, may yet be considered as a separate class from the unimprovable adults it was originally intended should be sent to Leavesden and Caterham.

So impressed were the Board in 1919 with the pressure on the accommodation provided at the Fountain for the most deeply defective cases (it being understood that the Fountain was, in fact, the only institution of its class in the country) that they proceeded to make arrangements for the provision of accommodation for unimprovable children of both sexes at Leavesden Mental Hospital, in upper wards where only the less robust and physically vigorous could be accommodated; thus this provision only slightly relieved the demands on the Fountain.

Training of Patients in Simple Occupations.

Early this year, however, the congestion had again become acute in certain directions; medical superintendents of the various institutions were consulted and the opinion was expressed that there might be found at Darenth a number of cases which after reasonable trial were not "trainable" in the sense given to that word at Darenth, but still were not "unimprovable" in the sense applied to that word at Leavesden and Caterham. It was decided to examine the records of the male patients at Darenth with a view to transferring all those who fell into this category to Caterham, there to be segregated as far as possible and employed in simple trades such as wood-cutting, land work, laundry work, &c. The idea was that if these cases were found to be susceptible of a higher degree of training in any particular industry, steps would be taken to provide facilities for such training at Caterham. Further, the advantage of transferring cases which were not likely to benefit to the fullest extent from the specialised accommodation at Darenth was obvious, seeing that at that time there were about 180 cases of mental defectives awaiting admission to Darenth all classed as "trainable." Thus, the first considerable change in the original arrangements for the reception of mental defectives was made, a change which seems to mark a step forward in the classification of these cases. To-day a number of the patients thus transferred to Caterham from Darenth are engaged in industries (such as carpentry) with what is looked upon by the medical superintendent as a remarkable degree of success. The system adopted has been to start classes of three or four pupils in a very small way without any idea of "forcing the pace" or aiming at output. The patients are encouraged to play at their work in the first place. When they become interested and begin to understand how to use, for instance, a hammer and a nail, they are allowed to make some simple object which will be of use and which they know will be of use. There are classes also in mat-making and tailoring, but it will be understood that the whole scheme is, at the present time, in embryo, and that it is too soon to suggest any very reliable inferences as to its future possibilities. I should say in passing, however, that a similar scheme is being adopted on the female side at Caterham among the young women, who are being trained to do more than had hitherto been done there in the way of needlework, rug-making, and so on. Results of these experiments are being carefully watched. The next step was to make further use of the vacant male adult blocks at Caterham by transferring thither the elder boys at the Fountain who had reached the age of about 9 years, and were found more suitable for male than for female nursing. A block was therefore prepared at Caterham and all the boys were transferred last spring.

An interesting feature of this change was provided by the statement made to the Board by the responsible medical officers that it was hard to say that any child was quite "unimprovable," and that it was in fact more correct to say that nearly all the cases at the Fountain hitherto considered hopeless were trainable to a greater or lesser degree. It was decided in future to reserve the Fountain for unimprovable boys under the age of 9, for unimprovable girls up to the age of 16, and for children of both sexes whether stated to be "trainable" or not up to 7 years. The reason for this change was that it was felt that there was need for a testing institution at which children could be observed so that their capacity might be more or less accurately measured before they were sent to Darenth. Previous to this arrangement all children of whatever age who were stated to be "trainable" had been admitted direct to Darenth, but it was found that so many were not really "trainable" in the Darenth sense that the accommodation there became as it were choked with cases which were not suitable, and which could not benefit by the specialised arrangements provided. On the other hand, the children admitted to the Fountain as unimprovable had, in some cases at any rate, been found to be so far superior to the original estimate of their capacity as to be suited for Darenth. At present, therefore, all children under 7 are admitted to the Fountain, where they are carefully watched, and after a longer or shorter period the medical superintendent of that institution consults the medical superintendent of Darenth with a view to the admission to the latter colony of all those whom experience has shown are "trainable."

---

[1] Being the substance of a paper read on Nov. 26th, 1920, during the Conference on Mental Deficiency and Special Schools at Church House, Westminster.

Christmas Toys for Sick Children.

This procedure of selection is, as a matter of fact, merely carrying into the working of the Mental Deficiency Act the scheme which has worked well in connexion with Lunacy Act cases. So far no use was made of Bridge Training Home under the Mental Deficiency Act. Cases there are all uncertified. Apart from school training at Darenth a very large number of industries are carried on; and the Metropolitan Asylums Board actually relies to a considerable extent for the toys provided every Christmas for the children in their hospitals upon the workshops at Darenth which make these toys from waste materials of all kinds. Leavesden Mental Hospital has been as far as possible turned into an infirmary for the harmless imbecile classes and to a large extent its inmates are Lunacy Act cases. The mentally defective children housed there are practically all paralysed or helpless, and, while everything possible is done for them, their infirmities are so many and so overwhelming that it is hardly possible to give them any instruction or training. But these cases are not to be taken as disproving the view that few cases can truly be spoken of as "unimprovable."

At the Fountain Mental Hospital the very lowest grade of idiot children is provided for, the common types admitted being the helpless, paralysed, and epileptic. It became evident soon after the hospital was opened that as many of these children were trained to feed and dress themselves, and in other ways become clean and even tidy and useful, some higher form of training might be attempted. To this end a school was started in 1917, a suitable teacher-nurse being selected to take charge of the children. She started by teaching them how to play, and gradually advanced them through elementary kindergarten work, musical drill, and singing with action songs and dancing, to doll-making, mat-making, and the dressing of dolls. This simple instruction may not appear to mean much, but in practice it is found to be economical in many ways, and, above all, the lives of these unfortunate children are made much brighter and happier. Every care is taken to select suitable nurses who are specially interested in children, and over them are fully trained sisters who work in conjunction with the matron and her assistant. After the children have been to school for a certain period they are subjected to special tests periodically by the medical officers with a view to selecting the best for further intensive training at Darenth.

No one who sees the children as they are on admission can fail to be struck with the remarkable change achieved in most instances after a comparatively short period. The patience and care lavished on these afflicted atoms can hardly be appreciated except by those who watch the work of the institution constantly.

I need scarcely say, in conclusion, that the Board are well aware of the splendid work done under Section 37 of the Mental Deficiency Act, by boards of guardians and combinations of boards of guardians at Monyhull Colony and elsewhere.

EXPERIMENTAL GIGANTISM BY FEEDING WITH PITUITARY GLAND.

WHEN growth continues beyond the normal size of the species the condition is known as gigantism. Clinically, evidence points to the conclusion that at least one form of gigantism is due to over-function of the pituitary gland. Attempts, however, to produce gigantism by feeding with pituitary have not hitherto been successful. E. Uhlenhuth, Rockefeller Institute, has continued his researches and has now succeeded in producing experimental gigantism. His experiments were made on salamanders, and the experiments showed that it is the anterior lobe alone of the gland which possesses the ability of maintaining growth after the normal size of the species is reached. The function of the posterior lobe is still unknown, since it is the intermediate part which supplies the extracts which excite unstriated muscle, produce diuresis, and raise blood pressure. The effect of the anterior lobe diet depends on the developmental stage of the salamander. Larvæ do not respond to it; the growth-promoting effect of the gland commences only after metamorphosis has taken place. Specimens of *Amblyostoma opacum* have been kept and measured for several years. After the first year the animals grow very little. The largest control animal in one group measured 115 mm., while the largest hypophysis-fed animal measured 138 mm. In another example the normal typical animal, 3 years old, measured 111·5 mm., and the corresponding control 131 mm. at 2 years of age. The feeding was begun after the animal was 1 year old. Similar results were obtained on the species *A. tigrinum*. Every single animal of this species fed on the anterior lobe outgrew all the controls and other normal animals raised in the laboratory. If the animals were fed on the posterior lobe growth was not only not stimulated, but even greatly retarded. Feeding with the anterior lobe causes: (1) a very marked acceleration of growth; and (2) a continuation of growth beyond the specific size of the species, resulting thus in hypophysis or pituitary gigantism. It is impossible to renew growth by feeding with large quantities of normal food after growth has practically come to a standstill. The continuation of growth beyond the normal size of the species is not due to an increased amount of food, and it would seem that at a stage where growth ceases or is greatly diminished under normal conditions cell proliferation can be actually enforced by the specific growth-promoting substance contained in the anterior lobe of the hypophysis.

THE BOLSHEVIST UNIVERSITY OF SARATOFF.

AT Saratoff, on the Volga, has been established the first free scholastic and socialistic University, of the ordinances of which the Italian journal, *Patologica* (xiii., 291, Jan. 1st, 1921, 3) reproduces the salient points. The aims of the University are apparently (1) to give the proletariat a communistic conception of the world based on rigorously scientific data; (2) to initiate the proletariat at the earliest possible moment into all the most recent discoveries of science by inducing it to seek ever new scientific paths; (3) to explain to the masses the intimate connexion between the so-called exact sciences and practical life; (4) to excite in them not only a burning zeal for knowledge but for action also; (5) to direct them towards creative activity on a scientific basis; (6) to guide, train, and attract towards activity creative of social reconstruction the more capable proletarian elements; (7) to create institutions qualified to develop in the citizens aspirations towards self-culture.

Systematic and special lectures have been organised, together with work in laboratories, scientific departments, libraries and museums, and scientific excursions will be undertaken. All citizens of both sexes over 16 years of age who can read and write may attend the University, and the students are divided into groups in accordance with (*a*) the state of their preparatory work and mental development; (*b*) their predilection for one or other branch of science; (*c*) their reference to some particular psychological type as determined by the application of tests.

The syllabus of instruction comprises (1) the Universe (Cosmology), (2) Man (Anthropology), and (3) Human Society (Social Sciences). Since the aim of the University is not only the development of the intellect but also the development of character, the fundamental principle of the socialistic University is the self-education of the students. To this end the University has organised a series of lectures on the development of the will power by auto-analysis (systematic self-observation) and by some degree of practical instruction applied by the student to himself. To make the teaching more homogeneous and to link up all the subjects taught, a chair of Methodology (the first in an institution of this type) has been created for the purpose of unifying the separate lectures and making them conform to the fundamental programme of the University—the attainment of a vast communistic interpretation of the Universe. The course will extend over two or three years and the lectures will be given during three hours on three or five evenings every week. In association with the University are libraries, laboratories, museums, excursion and information departments and means for liaison with other similar organisations. When every citizen possesses not only general knowledge but also a scientific grounding, is able to think and speak, to make scientific generalisations and researches, to think for himself and to illumine scientific concepts with the facts of daily life, the world should be a very different place.

The Hunterian Oration

ON

ASTLEY COOPER AND HUNTERIAN PRINCIPLES.

Delivered before the Royal College of Surgeons of England on Feb. 14th, 1921, the Anniversary of Hunter's Birth,

BY SIR CHARTERS J. SYMONDS, K.B.E., C.B.,
M.S. LOND., F.R.C.S. ENG.,
CONSULTING SURGEON TO GUY'S HOSPITAL.

WHEN your predecessor, Sir, in the chair invited me to deliver this oration—part of the Hunterian Festival—I felt misgivings as to my capacity to deal adequately with a subject which had occupied the attention of so many distinguished men. It seemed impossible to say anything new about Hunter, and, moreover, I had in 1892 dealt with his work in the annual oration before the Hunterian Society. It appeared to me, however, that this was an occasion when one might endeavour to trace the influence on others of one who by his sole effort had transformed professional outlook and teaching; to see how far his immediate pupils had carried forward his exploration into the untrodden fields of physiology and pathology. Let me first pay a tribute to the memory of the great biologist and surgeon whose birth we commemorate to-day.

HUNTER AS LECTURER.

When Hunter began his lectures in 1774, at the age of 46, it became obvious that a new era had arisen, a new conception of the processes of life, and of these as modified by disease, was being enunciated. These lectures he continued for 20 years—he died in 1793—and his doctrines gradually transformed the teaching in the schools, and thence in the profession, at home and abroad. For the first time surgery was taught as a science. The processes of healing and restoration of injured and diseased parts were shown to depend on the operation of broad and constant laws. He showed, moreover, that there is one pathology for medicine and for surgery; that medicine in its widest sense is one and indivisible, and must be learned as a whole. The physician must understand surgery, and the surgeon the medical aspect of disease. He was not an attractive lecturer, and the terms he employed being new to the older surgeons the attendance was small. He attracted, however, the younger apprentices, who, recognising the scientific value of the teaching, were not deterred by the obscurity of his style. Moreover, they found it worth while to attend year by year, for the new information forthcoming as the result of fresh experience and experiment sometimes reversed a previous conclusion.

Among the first pupils may be mentioned Abernethy, whose philosophic mind was well able to grasp Hunter's reasoning, and who became the chief exponent of his physiological discoveries; Astley Cooper, Blizzard, Chevalier, Anthony Carlisle, Everard Home, Henry Earle—all men who have left their mark on surgery and became teachers in the schools.

In the early orations there are many tributes to the scientific value of the teaching, and its effect in elevating the position of surgery.

Cline attended the first course when just out of his apprenticeship. He writes: "Having heard Mr. Hunter's lectures on the subject of disease, I found them so far superior to everything I had conceived or heard before, that there seemed no comparison between the great mind of the man who delivered them and all who had gone before him." Astley Cooper attended the lectures for several years, and writes: "His vast museum is a proof of what industry can accomplish, for it contains matter for seven years of investigation." It took Clift ten years to arrange the collection, and yet there was no confusion; every specimen was labelled and set in its proper order, for Hunter seemed to realise that it must be for others to build the structure which he had designed. He knew the malady from which he suffered—angina—and said that his life was at the mercy of any rascal who would make him angry. Yet he never relaxed his efforts. He felt there was a vast amount to be done and few to do it, and he therefore took every opportunity of communicating his observations to others, not by writing, but by word of mouth and of pointing out the path of progress.

Finally, let me quote the words of the greatest orator of our own time, Paget:—

> "The influence of such men as Hunter reaches far beyond the time and space of their conscious activity; their true thoughts live after them. Thus when we honour the memory of Hunter we honour not only that which is passed, but that which is still present—a still abiding power doing good."

It is now my object to trace in the career of one distinguished pupil—Astley Cooper—the influence of Hunter's teaching, and to show how the principles laid down were expanded and applied. It is becoming that I should choose a Guy's surgeon, for through Cheselden of St. Thomas's and Sharp of Guy's the Hunters derived their early instruction in surgery, and, moreover, we find in him perhaps the best exponent of the application of Hunter's teaching and one who did more than any other surgeon of the time to stimulate inquiry.

ASTLEY COOPER.

Time will not permit more than the briefest account of the long and busy life of this great teacher, who from the age of 17 till the year of his death at 74 never relaxed his investigations in anatomy, physiology, and surgery. He was endowed by nature with many fine qualities—courage, originality, a critical mind, power of concentration, a wise scepticism, and a lively imagination. He inherited splendid health, the value of which he fully recognised, and was blessed with a sense of humour, and a frank, open-hearted, generous nature. From his father, a clergyman, for those days of liberal thought and wide outside interests, he learnt the classics. His mother taught him history and grammar, and instilled into his mind religious principles, truthfulness, and a taste for literature; for she was an authoress of no mean repute. He was a high-sprited, attractive lad, fond of practical jokes, and showed none of the studious habits of his brothers who were sent to the university. The decision to apprentice him to surgery was made at the suggestion of his uncle and not from any predilection on the part of the nephew. The boy thus had a free youth, not over-taught nor overstrained, and had enjoyed the usual country sports. He had just completed his sixteenth year when he arrived in London in the month of August, 1784, to become apprentice to his uncle, Mr. Cooper, at that time surgeon to Guy's Hospital. He was a tall handsome youth, overflowing with high spirits, and soon became a favourite in the household of Mr. Cline, where he lived. It was usual for the apprentice to dwell with his master, but it was thought better for uncle and nephew not to be thus associated. Shortly afterwards, at his own request, he was transferred as apprentice to Mr. Cline, a circumstance having a far-reaching effect on his future, when the characters of the two surgeons are contrasted. His uncle was a fair anatomist, but as a surgeon followed traditional lines, and was too set to appreciate Hunter's teaching. He acknowledged that he could never understand him, and usually fell asleep at his lectures.

Cline, on the other hand, now about 38, was surgeon at St. Thomas's. He was a follower of Hunter, carried out his principles in his teaching, followed his experimental methods, was a good practical surgeon, and a man of sound judgment. He published hardly anything, and we know most about him from the frequent references of Astley Cooper. The democratic views held by Cline were inhibited by his apprentices. Such an influence was conducive in encouraging an opposition to tradition, and had its value, no doubt, in forming the mental outlook of Astley Cooper. Cline, no doubt, gauged the tendencies and character of the lad, who had exhibited no special leaning towards surgery, and set him a task in dissection which put him on his mettle. The performance was successful and the young student seems at once to have grasped the importance and interest of the subject, and from that time became an ardent anatomist. No doubt Cline, as he watched the progress of the dissection, which was made in his own house, pointed out the meaning of the structures exposed and directed the young observer to further inquiries.

He now threw all his energy into the study of anatomy and surgery, having the entry into both St. Thomas's and Guy's, which at that time were on opposite sides of the same street, the two hospitals being known as the Borough Schools. In scraps of autobiography he mentions his constant attendance at these hospitals and his habit of making notes of all important cases, and of taking every opportunity of attending post-mortems—then quite exceptional—and of examining the parts removed by operation. At Cline's suggestion, no doubt, he began attendance at Hunter's lectures, and had the priceless advantage of talking over the subject with his master and with other apprentices, one of whom interested him in botany and another in physiology.

In his indentures it was provided that he might spend a session in Edinburgh, and thither he went in October, 1787, in his twentieth year. He carried introductions to the leading professors, of whom, having heard much, he was anxious to see and hear. And he was not disappointed. Cooper was by this time a good anatomist, and, moreover, had spent much time at the bedside and had made careful notes of the cases, so that he was in a position to discuss both anatomical and surgical questions. From his frank and courteous manner, free from assertion, he was well received, and was made a member of the famous Royal Medical Society and offered the presidency should he return. He made good use of these seven months—spending his time in the infirmary, making notes of the cases, and attending lectures by Monro and others. "Being near them," he writes, "did not diminish the importance I had been led to attach to them from their public character." At Edinburgh he learned order and system, for which the teaching has always been famous, and under this guidance he planned a method of examining cases of disease which led to the surest and safest mode of forming a diagnosis, and this he pursued throughout his life to the advantage of his teaching and his practice.

Now comes his first appointment as a teacher of anatomy. He had proved himself an industrious and zealous student, and for some time had assisted his fellow students in their dissections. In 1789 he was appointed demonstrator of anatomy at St. Thomas's Hospital, and so well had he filled this important position that two years later he was asked by Mr. Cline to take a share in the lectures on anatomy and surgery. He was now 23 and not quite out of his seven years' apprenticeship; he had put into these seven years an immense amount of work and was well qualified to undertake the duties With Hunter he must have been on as familiar terms as any of his class, and had assisted him in the dissection of a whale. He had spent seven months at Edinburgh in close association with the eminent men at that renowned school. He had acquired at the Physical Society the art of speaking and discussion. When one adds to this record his personal charm, his fine presence, his interest in others, and his enthusiasm and love for his profession, one can hardly wonder at Cline's choice of an assistant.

Hitherto the subjects of anatomy and surgery were combined in the same lectures, a plan which Astley Cooper considered was injurious to both. After some hesitation Cline agreed to their separation, and in future the anatomical lecture was given daily from 2-3.30, and that on surgery in the evening at 8 o'clock. He now resolved to devote the next three years solely to [illegible]ing his knowledge of anatomy and surgery, [illegible] endeavouring to amplify his income derived [illegible] lectureship, by seeking private practice. This momentous resolve he was enabled to carry out, owing to his wife—whom he married this year—possessing a considerable fortune. Then followed a very happy domestic life, clouded, alas, in the early years, by the death of their only child while still an infant.

In his first course of lectures on surgery he followed the Hunterian model, but was disappointed to find that his class was inattentive, and suffered still greater disappointment when the number entering for the following year had decreased. Reflecting on the cause of this want of success, he realised that the men had been apprenticed for five years under surgeons taught on the old lines, and could not understand such terms as "action," "adhesion," "resolution" as applied to living processes. At these terms Hunter's own contemporaries had scoffed. He arrived at the quite sound conclusion that it was necessary for his pupils to have a considerable knowledge of surgery before they could comprehend the application of the principles enunciated by Hunter. He at once changed his method, and with immediate success. Cases of disease and injury were brought before the class, the cause and nature of the disease or accident described, with the appropriate treatment, and afterwards the physiological and pathological bearings applied and further illustrated by morbid specimens and experimental results. This method he pursued throughout his 40 years, enriching his lectures with cases from his own experience, and as this widened the lectures became more and more valuable. But never did he lose sight of the scientific side or relapse into the method of earlier lecturers, who dealt with cases only. Always inquiring by dissection, by study of disease in the living and the dead, and by experiment he was constantly improving his teaching. The lessons to be learnt from such vast inquiry were brought to the service of his class, and each year further light was thrown upon old subjects, and not from second-hand knowledge, but from the actual observation of the teacher himself.

So successful had his lectures become in his second course that when he began the third in 1793 the number of entries had doubled. In this year, at the age of 25, he was appointed lecturer at Surgeons' Hall. This was an annual appointment made by the Company of Surgeons. It was renewed for the next two years, when he resigned. The lectures were given on the bodies of executed "persons," to use his own terms, the theatre was constantly crowded and the applause excessive. With pardonable pride he writes: "I became a very popular lecturer." To further improve the education he very soon after his appointment promoted a society, confined to the pupils of the two hospitals, where cases of interest were shown and discussed. This existed for several years and was of particular value to the younger men, for the discussions at the Physical Society were beyond the range of any but the senior members of the schools. In a word, he devoted the first three years to the welfare of the students, and when one adds his personality, the buoyant spirits, the sense of humour, the hearty laughter, his readiness to help in their work, and his kindly advice and often assistance in more substantial ways, is it any wonder that he was sought after as a teacher and beloved as a friend. For nine years he continued these demonstrations and lectures, pursuing without intermission his studies in anatomy, comparative anatomy, and physiology. He had gradually obtained private practice, and by the end of the period his income from this source was said to amount to £1000.

In 1800 he was appointed surgeon to Guy's Hospital, thus securing the acme of his ambition at the age of 32. Objections were raised on account of his democratic associations, but the treasurer, Mr. Harrison, being satisfied that Astley Cooper had abandoned these political connexions, and convinced that he was the better candidate, allowed him to canvass the governors, with the result that he received their unanimous support. He was well equipped for the position, for though he could not have performed many operations, he had acquired from his dissections such a knowledge of anatomy as would enable him to work with accuracy and speed, and from his experiments on animals a refinement of technique not possessed by any of the other competitors.

[Sir Charters Symonds pointed out how the progress of surgery had depended largely upon the use of living animals, dwelling especially upon the present position of cerebral surgery, saying that further progress requires the same means of investigation, surrounded, of course, by due safeguards and in the hands only of competent persons.]

As a Teacher.

Astley Cooper was undoubtedly a great teacher and in this regard probably had a wider influence than anyone of his time. He no doubt possessed a natural gift for teaching, but this would not have gained him the position he obtained in this respect had it not been for his industry and his determination to enunciate no doctrine unless proved by observation and experiment. He was not a genius in any sense, and he himself attributed his success entirely to his industry. He had clear ideas how knowledge should be acquired, and constantly impressed upon his class the importance of personal observation. He recognised the evil effect of too much teaching and inculcated personal observation of the processes of nature.

> "If," he writes, "the method of observation be not pursued and too much attention be given to theory, they have (i.e., the students) afterwards, when they embark on their professional practice, not only everything to learn, but also to abandon those false impressions which hypothesis is sure to create. It is right, therefore, that those who are studying their profession should be aware that there is no short cut to knowledge."

He further lays it down that—

> "In collecting evidence upon any medical subject, there are but three sources from which we can hope to obtain it—from observation on the living subject, from examination of the dead, and from experiments on living animals. By the first we learn the history of disease, by the second its real nature so far as it can be certainly known, and by experiments on living animals we ascertain the processes resorted to by nature for restoring parts which have sustained injuries, and then apply that knowledge to accidents in man." "These," he adds, "are the only sources of true knowledge, and the deductions from these are the sole basis of legitimate theory."

MODERN MEDICAL EDUCATION.

This advice is as sound to-day as when it was uttered. Let us see how far we are conducting education by the method of observation. Our problems with regard to teaching to-day are even greater than in his time, and chiefly because of the immense increase in knowledge. Anatomy remains much the same—it is a finite subject; while physiology, and especially medicine—in its largest sense—have expanded enormously. Even anatomy as taught at present has become too heavy a burden for the average student. Has it not become too minute? Consider the enormous number of names to be memorised. Is it really necessary for anyone but a pure anatomist to know the exact attachment of all the muscles—for example, of those of the spine, the minute markings in the bones, to which side a bone of the carpus belongs, the whole account of, say, the lachrymal bone and to which side it belongs? Take the brain and central nervous system. Might not more than half be omitted? In all directions I would urge curtailment of the requirements in this subject for the pass examinations and a fuller study of the essential parts. Examiners may reply that they do not expect the candidate to know the whole of anatomy. But the candidate does not know this, and if he wishes to make sure of passing is obliged to cover the contents of a text-book. What is the result? He is not familiar with any part, and while he should be giving time to the larger and more important questions—to the coördination of muscles, to the bearing of anatomy on surgery—he is compelled to "get up," say, the otic ganglion and to be able to recognise any cross-section of the brain. Examiners complain that a candidate often fails to recognise an ordinary muscle, and I have seen one fail over the supinator longus. But is this his fault? I claim it is not, for he has little chance of making himself familiar with the structures in various attitudes because of the lack of opportunity. How can familiarity with anatomy be acquired when three men are engaged on one part? It is impossible to learn anatomy from pickles and wax models. But apart altogether from this deficiency in material I would urge a large reduction in the amount to be acquired. It would surely be possible to cut out a good third of anatomy without the omission of anything essential, or diminishing the instructive value of the subject. I appreciate the dislike of any anatomist to rest satisfied with less than the whole, but I fear he must be called upon to modify his desire.

Dearth of Subjects.

Observation in anatomy is being hampered by the lack of material. There were difficulties in obtaining material for dissection in Astley Cooper's time, and though since the Anatomy Act the supply has been regularised, the schools are again so short of material that the teaching is seriously imperilled. At the opening of the session last year, when the entries were particularly large, the supply was almost nil; urgent representations have been made to the Health Minister who now controls this question. In his reply he states that there is a sufficient supply of unclaimed bodies, and that pressure would be brought upon the guardians. It cannot be too strongly represented to the public at large that anatomical and surgical teaching is at present seriously interfered with. Operative surgery cannot be taught, and the practical examination in this subject for the final Fellowship has in consequence for the present been abandoned. Those in opposition to this essential requisite for instruction cannot be ignorant that it is impossible without dissection to educate medical practitioners, and more especially surgeons. They are acting against their own interests and the welfare of the community. Fresh legislation may be necessary, and this has been promised should the present effort be fruitless. I would here appeal to all who have any influence to press this matter upon the attention of those in authority.

Again, physiology has become such an enormous subject that it is impossible for any student adequately to cover the ground in the time at his disposal. The physiologists, many of whom are specialists in one branch—for you can only dig deeply in a narrow field—are the examiners. One can quite understand an examiner, an authority on, say, respiration, being dissatisfied with the answer of a student who has gained his knowledge from a text-book and sat under a lecturer whose chief interest is in the nervous system, and obtained most of his practical instruction from demonstrators. The time has come, indeed has long come, when some definite agreement should be arrived at between the teachers and the examining board as to what limit should be set for the pass examination in both subjects. Are not the rejections in these two subjects excessive? And yet the men, as a rule, are attentive, do their best, read the text-books, and yet fail. Why is this? Not, I believe, because the students are idle or lacking in ordinary ability, but because of the magnitude of the subjects. And yet when these men enter the wards the majority find no further difficulty and turn out capable practitioners. We can all as teachers in the medical schools recall really good men who have been rejected, in both these subjects and at the finals. In dealing with these matters we must always keep before us the capacity of the man with average abilities and the requirements for a pass examination. Far be it from me to advocate anything which would diminish the highest scientific culture to which we can attain; for this would be contrary to the teaching of Hunter and his pupils, who did so much to elevate the position of the medical profession.

But we have also to consider our responsibility to humanity and the call upon us to give our men such instruction in the limited time at our disposal as will not fail them at the bedside.

Evil Effect of the Prolonged Course in the Preliminary Sciences.

The effect, it seems to me, of the long course in the preliminary subjects on the mind of the average man is to check his powers of observation and fatigue his brain. He has to learn from a book the greater part of his work, to conduct chemical experiments according to plan, to dissect a worm guided by a diagram. In anatomy he must get up a host of things to be soon forgotten. What is the result? He comes to the wards after an all too brief holiday, often with the edge of his keenness dulled, with some of his best energy wasted, and without having had any opportunity of exercising independent inquiry or observation. The man with able brain and good physical power does not suffer materially, for he has found relaxation in outside reading, intellectual associations, and in exercise. In the majority both mind and body have suffered, the former from too narrow a course of study, which has cramped the powers and allowed no freedom of thought, the latter from too little recreation. The student inclined to take a by-path in physiology must forgo what would be a valuable exercise in order to keep to the syllabus, for the examination is always before him. In effect the student being a man is still under tutelage as a boy and, I submit, suffers injury. The only remedy is, I believe, first to reduce the curriculum to reasonable dimensions and then to bring the student early in contact with the sick and injured. Here he will learn to observe and have the opportunity of applying his knowledge as it is acquired. Consider, moreover, the immense value to younger men of having such a common ground for discussion, and of getting away from books and the routine of the class-room.

While by no means wishing to be understood as decrying the study of the collateral sciences—these handmaids of medicine—an acquaintance with which is indispensable, the question I would raise is this—Do they hold, as taught to-day, their due proportion to the later subjects? However well informed a man may be in the preliminary sciences, the final court of appeal is at the bedside. Here alone can he acquire familiarity with disease. The mental attitude of the patient must be studied, he must be considered as a man, as a sensitive being. The special reactions of each individual to his surroundings and to the disease from which he suffers must be noted. The student must learn to set a value on signs which are not to be estimated by any physical apparatus; in children to interpret the meaning of a cry, a restlessness, a refusal of food. Familiarity at the bedside can alone provide such knowledge. The student of medicine throughout his life must be sensible of the atmosphere which surrounds the sick-bed.

Is a due proportion of his time in hospital allotted to this most essential part of the curriculum? If not, then surely our method is at fault, and we are like to turn out men armed with all kinds of scientific method, but lacking that most necessary possession the power of interpreting the condition of the patient. When the time allotted to professional studies is considered, and when the range of these studies is taken into account, does there appear to be no danger, that, in some instances at least, that which is subordinate may in a great measure supersede that which is essential.

We constantly hear it said by examiners in the final subjects, who are at the same time teachers, that the candidate shows a lack of familiarity with bedside knowledge. He "has too much teaching," is "spoon-fed," his answers are drawn from the book and not from observation. If there be anything in this criticism, is it applicable to such a proportion of students as to compel attention to the mode of education? What proportion of the men preparing for any profession, given opportunity and a few directions, may be left to themselves, to extract the honey from the flowers? Is it more than 5 per cent.? Whatever it be, the majority require more direction, and if the result of our teaching in surgery is that 45 per cent. are rejected it does seem that, given average ability in the students, a defect exists, and must lie in the education, in the examination, or in some want of coördination between the two.

What characterises the man of ability is the power to observe, to coördinate, to contrast, and to draw deduc- [illegible] The average man possesses his share of these powers, but they have not been exercised, and our problem, especially in the clinical period, is to develop the power of observation. The only opportunity the student of medicine has for independent observation, it seems to me, is in the clinical field, and the sooner he is brought there the better.

Now let us look for a moment at the curriculum as a whole. The man who qualifies in five years must not fail at any examination. Of this period he has no more than 20 months for the study of the final subjects, and to accomplish the result he must hold appointments continuously. Only a very able man can get through in the time, and very few make the attempt. The majority take over six years, a good many seven years, to pass the Conjoint Board. Is there any wonder when one considers what he has to learn? What is to be done? It is clear to everyone that the curriculum is overloaded, and there are only two remedies: Reduce the subjects in the earlier studies or lengthen the curriculum. The latter no one desires, but there is, as far as I can gather, a general opinion that a drastic reform is needed in the time allotted to the earlier subjects, and more especially in their extent. I admit that, ideally, it looks well for the student to advance from the lower organic world to the higher, but I very much question whether it is not better for him to begin with human anatomy, leaving the study of the lower animals and vegetable world to be worked in with human physiology. Physiology is more important in the study of medicine than anatomy, and if curtailed in the earlier years is there any reason why it should not form part of the later period? I believe the student would gain immensely by such a change, for he would constantly be applying his knowledge—which would in this way be kept fresh—in the explanation of morbid processes. Moreover, he would be informed of the newer discoveries, for the knowledge of physiology is constantly advancing; it is not finite as is anatomy. We require, indeed, a new conception in the teaching of this important subject, and almost a new kind of teacher—one who has a practical knowledge of disease. There was a time when a physician lectured on physiology, and provided he did not carry on too long the plan was sound. The student was shown the application of the science. Is it not possible to get back to some such combination with physiology predominant? So one day we may see the physiologist at the bedside. Simplify anatomy in the early period, and in the later period let applied anatomy be taught by the professor in this subject.

Contrast for one moment the teaching in Astley Cooper's time—then the student came in contact with the sick and injured at once, and he learnt to apply his anatomical and physiological knowledge, and, above all, his powers of observation were being exercised. Have we improved in this? Personally, I am convinced that the sooner the student is brought into contact with the sick the better. It is satisfactory to see that in Birmingham the first-year men are shown examples of disease and injury, and that each year the time allotted in this way is increased. I hear that in the physiological lectures at one school in London patients are introduced to illustrate the effects of disease, a member of the general staff being associated with the lecturer on physiology. Under the unit system at one hospital the first-year men, I am informed, help in the out-patient work. It is a return to the days of Astley Cooper—from which we may extract something that may be useful to-day. My opinion is that we should reduce the time spent on the preliminary sciences, introduce clinical opportunities from the very first, and secure three years out of the five for the final courses.

Astley Cooper as Surgeon.

From the investigator and teacher let us pass to the consideration of the surgeon. As a surgeon Astley Cooper's name will always be associated with the ligature of arteries, for he it was who first put a ligature on the carotid; he was one of the earliest to tie the external iliac, and the only surgeon of his time to ligature the aorta. From his earliest days as an apprentice, and all through his life, he carried on experiments of all kinds, and to him was largely due the demonstration of anastomotic circulation. Hunter had ligatured the femoral for the cure of popliteal aneurysm in 1785, when Astley Cooper was in the first year of his apprenticeship to Cline. No doubt master and pupil talked over this revolution in surgery which has saved so many lives, and saw the application of the principle to other situations. During the years that followed he tied all the main vessels in dogs and other animals to prove the truth of the anastomotic circulation. Both carotids were held to be essential to the integrity of the brain in man and animals. The fallacy was soon dismissed as far as dogs were concerned, for he tied both vessels simply and simultaneously, without ill-effects, and later combined ligature of both carotids with double ligature of the vertebrals. This was generally fatal, but one dog at any rate survived. The performance of such a feat in half an hour was a tribute to the operator's accurate anatomy and technical skill. It was his custom also to ligature the carotid at his lectures to demonstrate the safety as regards the brain. It was, however, generally considered that such an operation in man was "impracticable or would be injurious to the functions of the sensorium." Cooper, however, had found a case where one carotid had been obstructed by disease, and Dr. Baillie had communicated an example of complete obstruction of one and partial of the other carotid without ill-effects. The defence of the operation put forward by Travers after his own operation shows the controversy that existed, and emphasises the boldness of Cooper's undertaking.

The opportunity long anticipated at last arrived, and it was on Nov. 1st, 1805, that he ligatured the common carotid in a woman. It was an advanced case of aneurysm, and occupied so large a space, that it was just a question whether there was room for a ligature between the sac and the clavicle. In the skilled hands of Astley Cooper, however, that was accomplished which few would have attempted. The patient died from suppuration of the sac 20 days later. Astley Cooper was not discouraged, for he had established two points: that the carotid could be safely tied and without injury to the brain. In reading the account before the Medico-Chirurgical Society on Jan. 29th, 1806, he says: "The failure was due to the operation being too long delayed, and ...... it will not prevent my performing it in any case in which the disease is somewhat less advanced." It is not difficult to imagine the criticisms that would be levelled by those who thought such an operation unjustifiable.

The second opportunity came on June 22nd, 1808, and was a complete success. In reading this case before the same society reference is made to experimental ligature "many years ago." On the death of this patient 13 years later from apoplexy the brain was obtained, and a drawing is given in Guy's Hospital Reports, Vol. I. Both these operations were carried out in the presence of several surgeons of the hospitals and some visitors, and one cannot but admire the courage of the operator's convictions. In both instances examination showed that no injury had been sustained by neighbouring structures. On the same day on which the second operation took place he ligatured the external iliac in an urgent case in which rupture was imminent. Eighteen years later the specimen was obtained at considerable expense and trouble, for the man lived in the country. I am able to exhibit to you the preparation, which displays in an admirable manner the anastomotic circulation.

Finally came the culmination of this work in the ligature of the aorta. The operation was performed on June 25th, 1817, by the transperitoneal route. In referring to his experiments, when reading the paper on ligature of the carotid, he says: "Lastly, I was anxious to ascertain when even the aorta was tied if the blood would still find its course by anastomosis." This he had demonstrated in dogs, and had repeated the experiments two years before—i.e., in 1815. "The animal," he says, "survived the experiment and maintained his usual health." In Medico-Chirurgical Transactions, vol. ii., will be found a coloured illustration of the injected specimen. Here is a specimen of Astley Cooper's showing successful ligature in a dog. Again, it was unfortunate that the case was an advanced one and the man greatly reduced by hæmorrhage. The story of this operation is dramatic, but time will not permit more than a brief summary. The aneurysm was of immense size and filled the left iliac fossa; operation by the route adopted on animals was impossible, and he determined, rather than that the man should be left, to open the abdomen, displace the intestines, and secure the artery above the bifurcation. With his usual solicitude he explained the position to the patient, who replied, "Sir, I leave myself in your hands." With that dexterity which was the outcome of his experimental inquiries, he then placed the ligature without, as it proved, any injury to other structures. Though the man lived only 40 hours, the right limb had recovered its warmth and sensation, but the left—the affected side—remained cold and discoloured. This he considered due to the pressure of the large aneurysm interfering with the anastomosing vessels. Astley Cooper in his comments, after referring to the fear of many that such an operation would be immediately fatal, writes:—

> "We had to lament not that the operation was performed, but that it had not been sooner done. Sorry indeed should I be," he adds, "to sport with the life of a fellow creature, who might repose a confidence either in my surgical knowledge or my sympathy."

Thus we see that he had broken new ground, had thought out the details of possible operations, had by experiment on animals proved that so far as they were concerned success was obtained, and therefore might be anticipated in man. "The secret of success in life is for a man to be ready when his opportunity comes."

[The orator here considered Sir Astley Cooper's contributions to knowledge in wider fields; his publications on hernia, on fractures and dislocations, and on the anatomy of the breast. Travel, museum study, and discussion, of which Cooper recognised the educative value, brought him into personal touch with such men as Desault and Chopart. The orator set out the value of collective observation as it was made clear in Cooper's experience.]

PERSONALITY.

He was accused by some of his contemporaries of ignoring the work of others, especially his predecessors. This he frankly acknowledges, for so much of the teaching being vague and traditional, he felt that progress could only be made by individual research. He, however, frequently acknowledges his debt to Hunter, to whom he owed most, and next to his master, Cline, upon whose sound judgment he sets great reliance. He calls him "my most able and judicious præceptor," and in the dedication of the first volume on hernia acknowledges "that many of the ideas which it contains have been derived from your public and private instruction." The active part he took in the discussion at societies shows his respect for the opinion of his contemporaries. Of the younger men he showed no jealousy: "If I am more proud of one thing than another it is of inspiring zeal in the rising generation; it is in seeing the Lawrences, the Traverses, the Stanleys, the Brooks, the Earls of the day, rising into eminence."

Both Hunter and Astley Cooper fully gave of their knowledge to others, and were not concerned who discovered the truth so long as it was found. Truth to them was bigger than person or school. He held with Kipling that, "The game is more than the man in the game and the ship is more than the crew."

I have incidentally mentioned many points revealing his personality. A glance at the portrait shows that he was a man who must have had a commanding influence on others, both morally and intellectually. Offending at times from the rapidity of his decision in diagnoses, he nevertheless compelled attention from his superior knowledge. Writing of himself in the third person he says his "strength consisted in the quickness with which he could decide upon the nature of a case, as well as the readiness with which he adopted his means of treatment. He was a good anatomist, but never a good operator where delicacy was required; for the operation of cataract he was never fitted by nature; for stone, aneurysm, hernia, and the removal of tumours prior to his giddiness he was excellent." These comments are somewhat disparaging when one recalls what he accomplished in the way of operations.

"His affection and consideration," says one of his dressers, a long and close friend, "brought comfort and confidence. In his behaviour towards his patients he set a fine example, explaining to the poorest in a kindly manner the nature of a proposed operation." When, however, he had made up his mind as to an operation there was no hesitation, and from his accurate anatomy and his skilful technique, he was rapid yet without hurry, accurate without delay, bold without rashness—essentials when we remember that there were no anæsthetics. He was generous in dealing with those to whom a fee meant a good deal. From the officers of Wellington's army he declined remuneration, explaining that as they had fought and endured hardships while he had benefited by the protection thus afforded, the least he could do was by showing his gratitude in the only way in his power.

Time will not permit even a list of the many honours conferred upon him at home and abroad. He was serjeant-surgeon to two sovereigns, upon one of whom he performed an operation, receiving a baronetcy in 1821. Two tributes, however, deserve special mention—the portrait which is before you, subscribed for by his old pupils, and the statue in St. Paul's erected at the expense of the senior members of the profession. The portrait by Sir T. Lawrence exhibits Astley Cooper somewhere approaching 60, and is considered the chef d'œuvre of this great painter. It is interesting to compare it with that of Hunter; both are looking up and into the future, both see much to be done—Hunter the philosophic genius and Cooper his great pupil, ready for any emergency.

He died in 1841 at the age of 74, having extended and upheld the reputation of British surgery for half a century, and was buried beneath the chapel of the hospital he loved so well and whose fame he did so much to extend. By his will he founded a triennial prize, and it is significant that he directed that the first subjects for inquiry should be upon the thyroid, the spleen, the thymus, the suprarenal capsules, and the state of the blood and blood-vessels in inflammation, all subjects on which he had himself made observations and conducted experiments. He foresaw that future workers, better equipped, would unravel the secrets which had baffled him.

The Hunterian era awoke in the minds of men a desire to explore the old ground by new methods, and to unearth the truths so long concealed. There was a spirit of adventure, like that which animated the Elizabethan explorers, the ambition of the healthy human intellect to extend its range of vision and knowledge.

To Hunter belongs the credit of the discovery of this new world. He it was who lighted the torch, and I hope I have shown that Astley Cooper was amongst those who first carried it forward in the race, kept it alight, and then passed it on not only undiminished, but burning with a brighter flame; and so when his course was run the goal was nearer for the part he had taken. "After brief life men die, and like runners in a race hand on their torch to another."

SUSSEX THROAT AND EAR HOSPITAL.—Reference was again made at the annual meeting of the governors of the Sussex Throat and Ear Hospital at Brighton on Feb. 5th to the need of an additional wing, but the proposal has been abandoned until better times. Rearrangement of the present accommodation, however, has provided five or six additional beds. The demands upon the hospital have again been very considerable during the year. Out- and in-patients have made increases in their payments during the year, the total increase from in-patients (500) amounting to £76 9s. 6d., and from out-patients (5000) to £32 9s. 11d.

An Address

ON

SKIN DISEASE

IN RELATION TO INTERNAL DISORDER.

Being the Opening Address delivered at a Discussion held on Feb. 14th, 1921, by the Medical Society of London,

BY SIR JAMES GALLOWAY, K.B.E., C.B.,
M.D. ABERD., F.R.C.P. LOND., F.R.C.S. ENG.,
SENIOR PHYSICIAN, CHARING CROSS HOSPITAL.

THIS subject has been attractive to trained and untrained minds from early times, and has proved to be sufficiently alluring to stimulate the interest of some of the most esteemed members of our own calling. I need only recall to your memory the work done in this field by members of your own school of medicine—Thomas Addison, Charles Hilton Fagge, and Philip Pye Smith; by others such as Jonathan Hutchinson, Stephen Mackenzie, and William Osler; the special studies by Henry Radcliffe Crocker, and by a secretary of this society whose knowledge of clinical medicine and whose personal character had a great and abiding influence on his colleagues and friends—Thomas Colcott Fox.

LOCAL CUTANEOUS INFECTIONS.

The attraction of this field of study to the trained physician is no doubt partly due to the fact that the knowledge of external and visible signs may lead to the interpretation of their hidden cause, the recognition, it may be, of a mysterious malady, to its treatment and the restoration to health of the sufferer. But the diseases which affect the surface of the body are in many cases the malady itself, and its cause need not be sought further afield than in the lesions which are visible. This is notably the case in many external infective diseases, and in certain of the abnormalities of growth and degenerative processes to which the skin is liable. Examples of these morbid states of purely local origin are the diseases recognised to be due to external parasitic infections, the diseases of the "ringworm group," for instance, due to growth in the skin of various hyphomycetes; many of the inflamed conditions of the surface included under the term eczema, and due primarily or secondarily to infection by pyogenic bacteria; in all probability also the inflamed and desquamative conditions of which psoriasis may be taken as the type disease. Examples of abnormal growth of tissue cells and of various forms of degeneration are seen in the primary neoplasms of the skin of epitheliomatous and other types.

All these may be considered as diseases affecting the integument itself. Their diagnosis, treatment, and prognosis demand chiefly an accurate knowledge of the structure and functions of the skin. In all such diseases, however, due, as we believe, to local causes only, he would be an unskilled physician who refused to take into cognisance the physical condition, the idiosyncrasies, and the mental state of his patient, and the manner in which these react on the external malady. Anyone who has seen the grave results of pyogenic infections in patients suffering from glycosuria, or of the extension of psoriasis during development of the later stages of pulmonary tuberculosis, and anyone who has made efforts to treat this disease of the skin in the case of patients suffering from certain forms of arthritis, will not require to be convinced of the influence exerted by general or internal disease on what appears to be a local cutaneous malady. "The conditions which modify the characters of inflammations of the skin and their influence on treatment" were ably discussed by Radcliffe Crocker in his Lettsomian lectures to our society (1904).

Passing from maladies, of which we believe the causes to be entirely external and local, and on which health and disease exert influences by raising or depressing the powers of resistance and of healing, I wish to draw attention to cutaneous manifestations in many cases even more striking, but which must be regarded as phases or results of a general infective process or of some internal disorder.

THE ERYTHEMA GROUP.

The first group of cutaneous diseases to which I would draw attention is the "erythema group," a class sufficiently well defined for purposes of clinical recognition. The various forms of reddening produced by merely local, mechanical, or bacterial reactions are excluded. On the other hand, the manifestations of this group may be not only erythematous but also urticarial, exudative, vesicular, and hæmorrhagic in character.

Acute Exanthematous Diseases.

The eruptions of the acute exanthematous diseases first attract attention. In the case of some of these diseases the eruption appeared to be so important a feature in the minds of our predecessors that it may well have seemed to be the disease itself, hence we have such names as rubella, morbilli, scarlatina, and the varieties of pox. So soon, however, as modern ideas concerning the origin of infectious diseases were conceived, it followed that the visible eruptions came to be regarded only as a phase or as one result of an infective process, and to be considered merely as a sign of the disease itself, the true cause being capable of producing more extensive and serious results than the eruptive phenomena. The later development in our ideas of infection, the possibilities of lessened or increased sensibility of the tissues and of the organism to toxins of various sorts, including foreign proteins not in themselves primarily toxic, naturally caused doubt as to the actual origin of these exanthems.

At the present time the most reasonable explanation seems to be that the special eruptions of these diseases result from the direct action of the infecting elements, protozoal or bacterial, on the skin. The chief considerations which led to these conclusions are first that the eruptions are very distinctive. They differ from each other sufficiently in the case of each disease to be fairly easily distinguished so that they form an important factor in the diagnosis. The eruptions which form a part of the reaction of the organism to bacterial and other protein poisons conform to one type—namely, the type of the urticarial, erythematous, and exudative erythemas. In the case, however, of the exanthems, the types of eruption differ sufficiently to be clearly recognisable, as in the case of scarlet fever and of chicken-pox, and the distinctive eruption is "true" to the set of symptoms which we recognise as indicating the malady in any individual case. The second important consideration is that in the case of certain of these diseases the organism recognised as the cause of the disorder has actually been found in the exanthem, as in the case of enteric fever and of syphilis.

It is important and suggestive to remember that in the case of many of the specific exanthematous fevers other eruptions than those considered to be specific do occur at various stages in the disease, sometimes early, usually late. These eruptions are of the erythematous type, possessing the characters of general erythematous reactions and without the specific features.

Action of Alien Proteins.

Much interesting and important information has come to us from the study of the effects of the action of alien proteins on the tissues and on the organism. As is well known, some of the results which have been obtained experimentally are of the most dramatic character. In addition to the very serious effects upon the nervous, the cardio-vascular, the respiratory, and the gastro-intestinal systems, it is well known that an important series of skin phenomena occur. These consist of eruptions varying from transient urticaria and erythema to changes involving destruction of the walls of the small blood-vessels, exudation of the blood contents, and later, it may be, to reactionary changes in the tissue elements of the skin. From the point of view of the clinical symptoms, these phenomena resemble closely the eruptions of the erythema group.

In the case of certain infective fevers, special opportunities have arisen for the careful study of the effects of such proteins as a result of the use of alien antitoxic sera in treatment. The serum sickness which may result, its symptoms and consequences, may be considered as a fair example of the reaction of the body to the introduction of alien proteins. In this remarkable condition it is well established that there occur variations from the "normal" reaction, due to what is apparently increased or diminished sensibility of the organism to the action of the alien protein. These variations from the normal seem to exist as a congenital or a natural disposition in a small number of individuals, but more commonly the condition is artificially acquired, and appears to be due to the influence produced by previous administration of the same alien protein. There is thus presented to us a set of phenomena very different in nature from those of an ordinary infection, though it is probable that these conditions of over and under sensibility are closely related to the biological conditions underlying what we understand to be immunity or proneness to disease.

Two facts stand out clearly for our recognition from the clinical point of view: First, as the result of absorption of proteins alien to the invaded organism, eruptions make their appearance closely similar to the erythema group of skin diseases; second, that these eruptions vary in degree, severity, and time of incidence, and these variations depend on stages of increased or diminished sensibility which may be acquired by artificial methods. Recognising these salient points, we may see how large is the field of medical investigation which they indicate; moreover, they may serve to point out the path through a field of clinical medicine which is as yet little known.

Exudative Erythema.

Let us take examples of cutaneous eruptions as seen in clinical practice, and inquire what explanation can be given of their origin in terms of our present ideas of the effects on the tissue elements produced by parasitic infection, or by the action of alien protein poisons. The type of disease to which I now refer is erythema exudativum multiforme. This disease shows very similar and very characteristic manifestations throughout the range of its incidence. It consists, as is well known, of erythematous and urticarial eruptions associated with œdema and other forms of exudation, sometimes showing vesication, and is occasionally purpuric. An important feature of outbursts of the disease is the tendency to localisation of the lesions to certain localities, such as the extremities, the face, and extensor surfaces; in many cases considerable areas of unaffected skin extend between the reacting or damaged tissues. This disease has long been suspected to have relations in the sense of cause and effect with certain generalised infections or localised centres of disease. Sir William Osler was much interested in tracing these connexions, and reported a series of cases during a period of several years in which the occurrence of erythema exudativum was associated with visceral lesions. These internal conditions were various, some of the cases showed disorders of the gastro-intestinal tract, others showed cerebral symptoms, in some there was co-existing evidence of serious damage to the kidney, and in one or two evidence of localised inflammatory disease. By attempting to establish the frequency of the association of the two morbid states, external and internal, he sought to suggest a causal relationship. With our present knowledge it is, at any rate, intelligible that such a relationship exists. In the case of localised inflammatory visceral lesions we know that various toxins are formed, bacterial or protozoal in origin. These toxins, which exist within the parasitic cells, and on the dissolution of these cells find their way into the surrounding fluids, pass into the circulation and are capable of affecting the structures of the invaded organism, either generally or in areas specially liable to injury In the case of the bacterial products it is known that they have various destructive influences. Amongst the better recognised are the neuro-toxic, the thrombotic, and the hæmolytic toxins, and it is also known that they have a special power of damaging the endothelium of the capillaries and the small arterioles. Such poisons arising from any infective focus in the body may act on the tissues in a very direct fashion analogous to the action produced by such toxins as those of the "venin" group. It is, therefore, not a matter of surprise, given a focal lesion, such as suppurative inflammation of the naso-pharynx or a circumscribed empyema of the pleura, that toxins are liberated which will produce damage to the endothelium of capillaries, associated with hæmolytic or thrombotic effects, in certain areas specially liable to damage, and thus cause the manifestations as we see them in exudative erythema.

Disorders of the Gastro-intestinal Tract.

In the case of the disorders of the gastro-intestinal tract, which are apparently so frequently associated with these cutaneous manifestations, the same influence of bacterial origin may be at work. Bacterial or other parasitic toxins escape from the gastro-intestinal tract into the circulation and produce the changes at a distance such as those already mentioned. It is, however, possible that in the case of the gastro-intestinal tract another cause of poisoning may exist—namely, that the damage to the gastro-intestinal tract may permit of protein substances passing into the circulation directly from the food. These proteins do not pass through the stages of normal digestion whereby they are rendered safe and useful to the body, but escape into the circulation more or less in their original form with comparatively unaltered protein molecules, and thus act as alien proteins. There is plenty of evidence of the highly toxic effects produced by the parenteral introduction of alien proteins; substances passing into the circulation from the gastro-intestinal tract in the way suggested may act in a similar manner. It is in this relationship that the studies of the reaction of serum sickness are so suggestive and valuable. The erythematous eruptions which are found associated with gastro-intestinal disturbance resemble closely the eruptions in the skin following the introduction of alien proteins in the form of antitoxic and other alien sera. In the case of both sets of poisons, the toxins of parasitic origin and the alien proteins, the possibility of increased sensibility or of diminished sensibility must be borne in mind.

We have, therefore, presented to us the very important suggestion that general or focal infections are capable of admitting into the body toxins producing destructive influences, and also that substances resembling more closely the alien proteins producing the protein reactions—serum sickness and analogous conditions—may also find their way into the circulation in visceral disease. Both these sets of poisons are capable of damaging the tissues, especially the blood and blood-vessels, in such a way that the diseases of the erythema group may be understood to occur. Many of the clinical phenomena, such as the distribution, incidence, the recurrence of these cutaneous manifestations, can be explained by the possibility of increased or diminished sensibility of the affected organism.

Erythema Nodosum.

Erythema nodosum is a remarkable affection possibly related closely to the erythema multiforme group. As is well known, this manifestation has long been suspected in this country to have special relationship to rheumatism. Sir Stephen Mackenzie was a strong upholder of this view, and by recording a series of cases in which the conditions co-existed he sought to suggest their causal relationship. I had the advantage of being his house-physician, and I recollect that he would declare on examining a case of erythema nodosum that there was no need to search further for the nature of the disease from which the patient suffered—that the eruption on the skin was as much evidence of rheumatism as the peculiar arthritis, or an attack of pericarditis or endocarditis. Probably most of us at the present day would not uphold the proposition in such an uncompromising manner. Erythema nodosum occurs in cases where there may be no other evidence of acute rheumatism. Failing to recognise the evidence of acute rheumatic fever, it would be unwise to bind erythema nodosum and rheumatism too closely together. But erythema nodosum is remarkable among the erythemas for the constant similarity of the lesions constituting the disease, differing considerably from the features of a typical "erythema." It may be possible that erythema nodosum is a "true" eruption, a manifestation of a specific circulating poison producing local damage, just as the special eruptions of the specific fevers.

Lupus Erythematosus.

There is another disease not properly included in the erythematous series to which I must call attention in this place—namely, true lupus erythematosus. This disease shows certain relationships with the erythematous group in the manner of its occurrence and in the area of its distribution, but it varies widely from the erythema type inasmuch as the lesions are long lasting, and that a certain amount of destruction of tissue is ultimately noticeable. In addition to the long-lasting erythema fibroid changes make their appearance, so that a certain amount of scar is noticeable to the naked eye in a large majority of cases. This disease has long been suspected to be the result of a general infective process. The absorption of toxins from quiescent tuberculous foci is thought by some to be the cause. On the other hand, the disease occurs sometimes in its most widespread and most dangerous manifestations where there is no evidence or suspicion of tuberculosis in the ordinary sense. One of the most severe cases in my own experience occurred in a patient who gave no evidence of tuberculosis, but who developed marked signs of cirrhosis of the liver soon after the appearance of the widespread eruption; to the effects of this disease she ultimately succumbed.

New and interesting information as to the cause of this mysterious skin infection has recently been obtained by the observations and experiments of Dr. Harold Barber. Dr. Barber has found lupus erythematosus coexisting with localised pyogenic infections. In one remarkable case he was able to prepare an autogenous streptococcic vaccine from the excised tonsils of a patient suffering from lupus erythematosus. The use of this vaccine provoked marked local reactions on the skin lesions, a result which is perhaps not to be wondered at; but more important was the fact that the continued use of the vaccine was followed by the disappearance and cure of the cutaneous malady.

The Pemphigoid Group.

There is another group of skin affections to which I would draw attention in this relationship, the so-called pemphigoid group, of which dermatitis herpetiformis may be looked upon as a type. In these cases there are eruptions on the skin of very similar type, localised erythema and urticaria, followed by various degrees of vesication, and frequently associated with pain or disturbance of sensation in the affected parts. This disease has long been suspected to be due to toxic processes of internal origin. Perhaps the most remarkable of the forms of the disease is that occurring in pregnancy known by the name herpes gestationis or the dermatitis herpetiformis of pregnancy. I do not think that anyone who has had the opportunity of seeing such a case, and of noting its coincidence with pregnancy, its waxing and waning with the period of gestation and the puerperium, can avoid the conclusion that the two conditions are intimately related. It is only recently, however, that any approach to a definite explanation has offered itself. With our knowledge respecting the relationship of the embryonal and maternal structures it is fair to assume that embryonal cells and their products may act as an alien protein. During the process of growth and absorption of the placental villi the proteins of the syncytial layers may be absorbed into the maternal circulation producing poisoning directly, or, on the other hand, a process of sensitisation of the tissues of the mother may take place, and at certain stages of pregnancy, due to the absorption of syncytial proteins, there are produced the lesions of the skin characterising one of the most distressing of the complications of pregnancy—namely, herpes gestationis. That the duration and severity of the disease increase with successive pregnancies is a strong suggestion that the maternal tissues become sensitised to the proteins of the embryo.

THE SKIN AND ITS BLOOD-VESSELS.

That the skin depends immediately for nutrition on its blood-vessels is obvious, and it has long been recognised that destruction of the skin and underlying tissues of the most severe nature occurs as the result of disease of arteries and veins. Morbid conditions due to stagnating peripheral circulation, such as redness, cyanosis, and œdema of the extremities, with alterations in the secretions of the skin, are not only unsightly and difficult to bear, but they produce weakening of the surface, so that pyogenic infections easily occur with serious consequences. These conditions are most commonly seen in the extremities. Rarely a similar state may be observed affecting the whole surface, associated with tachycardia and low blood pressure. The sufferer is in miserable health and death occurs from this cause alone. Such disorders of the circulation show certain similarities to true Raynaud's disease, though the pathogeny may be very distinct. Disease of the skin associated with functional disturbance of the blood-vessels requires much further observation and study before we can profess to understand its causes.

Thrombo-angeitis Obliterans.

Disease of the blood-vessels causing obstruction to the supply or to the return of the blood produces more easily understood changes from malnutrition, secondary pyogenic infection, and necrosis. Thus it may be claimed that the cause of gangrene of the extremities associated with senile, syphilitic, and other forms of occluding arterial disease is fairly well understood. There are, however, types of the disease concerning which our knowledge as to causation is still very defective. The noteworthy example is the strange disease of the blood-vessels causing necrosis of the extremities recently drawn attention to by Leo Buerger in New York and Parkes Weber in London. The condition, to which the name thrombo-angeitis obliterans has been given, occurs in young persons, nearly always of Jewish race. It appears to have no relationship with the ordinary causes of arterio-sclerotic change of the blood-vessels; its actual cause is still a mystery. The conditions which I have mentioned are the results of serious functional disturbance or of gross structural damage to larger blood-vessels. We are apt to forget that the supply of blood to the skin depends upon the minute blood-vessels, and that these small blood-vessels suffer degenerative changes, due to syphilis and other causes, just as those that are large. Microscopical examination gives evidence that the smaller arteries of the skin may be extensively diseased and disorganised; under these circumstances the skin, in spite of a fairly free collateral circulation, is badly nourished. The results are seen chiefly in the extremities; the skin becomes parched, the epidermis desquamates; coincidently, the white and especially the yellow elastic fibres degenerate, so that the skin loses its elasticity, and is seen to be in fine crackled wrinkles and folds. Under these circumstances pyogenic infection readily occurs; a spreading dermatitis, usually superficial and mild in degree in the first instance, is established; the condition then becomes described as "eczema," and the patient may be treated for this secondary result alone. Probably the state of affairs which I have outlined is the real basis for the condition spoken of by our predecessors as "gouty eczema." The spreading pyogenic dermatitis which we see is a secondary phenomenon only; the malnutrition of the skin, owing to sclerotic degeneration of the superficial blood-vessels, is the real disease. The generally accepted rules of treatment of many of the eczematoid diseases occurring in adults and older people require reconsideration. The local use of drugs supposed to have antiseptic effects in most cases does more harm than good; the fact that the eczematous state may be a secondary result of the vascular degeneration should be clear in the mind of everyone who is called on to treat such cases.

Permanent Dilatation of Arteries and Capillaries.

A very remarkable change in the superficial blood-vessels may be seen from time to time. It consists in permanent dilatation of the small arteries and capillaries, sometimes known as "nævi," but more accurately as telangiectases of various forms, affecting both the skin and mucous membranes. In some cases these occur in family groups, and there may under such conditions be a congenital weakness of the blood-vessels permitting these superficial dilatations to be formed. When these telangiectases are situated in the naso-pharynx or in other mucous surfaces the hæmorrhages may lead ultimately to fatal results. Some of these patients have been apparently wrongly considered to be examples of hæmophilia. In addition to this type, in which congenital defect seems to be the cause, very similar conditions producing widespread telangiectatic degeneration of the blood-vessels of the skin and mucous membranes occur in the course of long-lasting infective disorders, probably of diverse origin. Many of these cases, and perhaps the most severe, have been noted in connexion with infective conditions producing cirrhosis of the liver. They may form true angiomata with a central pulsing artery of supply surrounded by a lace-like network of dilated capillaries and venules. It may easily be understood that profuse and dangerous hæmorrhage may arise from injury to these angiomata.

THE SKIN AND DISEASES OF THE NERVOUS SYSTEM.

The nervous system, both central and peripheral, has long been held responsible for exerting influences on disease of the skin. It is easy to understand the way in which such opinions were formed. The skin is not only the integument, but, in addition to its other functions, is an organ of sense. It would thus easily occur to the minds of men that a close relationship existed when it was noted that injuries to nerves or to the central nervous system were associated immediately with alteration in cutaneous sensation—intensification, diminution, or complete loss—and it would not be difficult to conceive that the nervous system controlled the blood-supply of the skin, permitting of flushing, swelling, blanching, and shrinking as the effects of emotion, of excitement and terror, were noted. But although this co-relation of observations might well bring about the formation of the opinion, it is not an easy process to trace the actual influence of the nervous system on the tissues of the skin, even if such influences are strongly suspected to exist in individual cases.

Herpes Zoster.

The most noteworthy instance of close relationship is the interesting and well-known disease herpes zoster. The present evidence seems to establish clearly that this disease of the skin is associated directly with a peculiar, often hæmorrhagic, inflammation of the posterior root ganglia of the spinal cord and the analogous ganglionic structures. The peculiar destruction of the ganglionic cells is associated, on the one hand, with *degeneration of their nerve connexions with* the spinal cord; and, on the other hand, with changes in the neurons passing through the peripheral nerves to the skin. The very peculiar and characteristic lesions on the skin are slight, severe, localised, or extensive, depending upon the amount of damage to one ganglion or neighbouring ganglia. The well-known pre-herpetic, and especially the post-herpetic, neuralgia is evidence of the injury not only to the root ganglia, but to their nerve extensions. Accumulating evidence seems to point to the whole series of these morbid conditions being due to an infective process, of which the main brunt falls primarily on the ganglionic structures. It follows that true herpes—herpes zoster—must be distinguished from somewhat similar eruptions with more or less clinical resemblance, such as the so-called "symptomatic" herpes occurring in pneumonia and certain other infective diseases.

Syringomyelia.

The series of cutaneous reactions and injuries associated with disease of the spinal cord and brain are, however, not so easy of explanation. The organic disease of the nervous system in which the cutaneous changes have received most attention is syringomyelia. In this condition it will be recollected that as the result of congenital malformation or of acquired conditions, an excess of neuroglia, resembling glioma, is found in parts, or it may be throughout the whole extent, of the spinal cord and its continuation into the brain. This new tissue is found in relation to the position of the original neural tube, and occupies, therefore, the posterior fissure of the cord, involving the central canal. The result of the formation of this abnormal tissue or of its degeneration is that important tracts of the spinal cord, through which sensory impulses coming from all parts of the surface are conveyed upwards to the brain, become dislocated and destroyed. It is probable that the structures controlling the nutrition and vascular supply of the skin may also become disorganised. The signs of this peculiar lesion appear in the extraordinary sensory cutaneous symptoms occurring in syringomyelia. From the clinical point of view two main symptoms are prominent: first, interference with the control of blood-vessels, especially the blood-vessels of the peripheral parts of the body, permitting of phases of relaxation, with redness, swelling, and œdema, or of spasm of the blood-vessels, when there may occur blanching of the extremities. Usually flushing of the extremities, with cyanosis, is the most marked feature. In process of time atrophic changes take place both in the epidermis and the cutis. With the disappearance of the œdema the very characteristic appearance described as "glossy skin" may be seen.

The second and even more striking series of clinical changes is due to the remarkable alteration in sensation. This is due to the fact that the position of the morbid lesion on the cord is capable of producing dissociation of sensations. The forms of tactile sensation early in development, such as of ordinary contact, and pressure—"muscular sense"—the knowledge of position in space and the shape and size of objects handled, may remain intact, while sensations, such as of pain, heat and cold, and superficial touch are lost.

It can thus be easily understood that patients suffering from this disease are extremely liable to unconscious injuries to the affected areas; they have lost the protection afforded by the appreciation of pain, heat, and cold; and the loss of vaso-motor control with consequent œdema and malnutrition permits of easy and severe pyogenic infection. In this way occur the painless whitlows, the destruction of the skin, the loss of deeper parts, injury to nerves, disorganisation of the joints, and the phenomena observed so closely and described in such an interesting manner by Dr. H. Morvan of Lannilis.

Although these disorders are witnessed perhaps in their severest forms in syringomyelia, changes of similar character occur in other diseases of the nervous system influencing the vascular supply, the nutrition, and the sensation of the body.

THE SKIN IN RELATION TO DISORDERS OF ABDOMINAL AND OTHER VISCERA.

From this wide field only a few examples can be taken. It is a matter of surprise, considering the close physiological relationships which exist between the kidneys and the skin, that disease of the kidney is not more often associated with manifestations on the skin. On thinking over the large number of cases of Bright's disease of various types which come under observation in hospital and elsewhere, very few examples occur to mind of skin outbursts occurring in the course of the renal disease. Certain erythematous eruptions do ually occur, and have been mentioned by s writers. Two important considerations require to be noted. In cases of severe disease of the skin, especially in cases of exfoliative dermatitis, albuminuria and nephritis occur. This complication has been frequently noted both in the case of children and in adults, and is not a matter for surprise. It appears that in cases of exfoliation of the epidermis the risk of generalised infections is intensified by the fact that these patients are unusually liable to chills and cold. Such patients should always be protected against cold in the most careful way possible. The appearance of albuminuria in such cases is always dangerous and not infrequently leads to a fatal result. The second observation in this connexion is noteworthy. On reading the series of cases of erythema multiforme collected by various authors, it is by no means infrequent to find a record of albuminuria, hæmaturia, and nephritis. I think the presumption in such cases is that the cutaneous disease and the renal disorder are manifestations of the same toxic cause and that it is not correct to assume that the symptoms on the skin are caused by the disease of the kidney.

Xanthoma.

Many remarkable manifestations on the skin occur during the course of disorders of metabolism. One of the most interesting of these is the condition known as xanthoma. It is probable that the varieties of this condition are all associated with functional disturbances of metabolism. The most important type is that known as xanthoma tuberosum multiplex, which occurs so comparatively frequently in cases of glycosuria that sometimes it is described as xanthoma diabeticorum. But it may be seen in patients who show no glycosuria, though in such cases there may be indications, functional or structural, of disorders of organs such as the pancreas and the liver. The histological structure of xanthoma has been carefully investigated on many occasions, and at first was not easy to understand. The tumours consist of aggregations of newly formed cells conforming in type to the cells of the connective tissue, sometimes containing more than one nucleus; to these the name of xanthoma cells has been given, lending an air of special mystery to this peculiar growth. The cells suggest a reaction of the connective tissue to a mild non-pyogenic irritation. The interesting feature is that within the cells and in the intercellular spaces and channels granules of a fat-like material are to be seen. The tissue, as is not surprising, gives reactions indicating the presence of cholesterin, and it is said that cholesterin crystals or granules may also be seen.

The trend of these observations seems to point to the fact that in glycosuria and in allied conditions substances derived from the imperfect metabolism of the fats may be deposited at certain vulnerable points in the body, and by their presence produce local irritation of the connective tissue cells. Or, on the other hand, that poisons due to metabolic errors may damage these areas, and that the lipoid substances are formed locally in consequence and aid in the production of the characteristic xanthoma nodule. If this is so in the case of xanthoma it is probable that other reactions of somewhat similar type occur. In this connexion I should like to draw attention to the fact that lichen planus seems to occur with undue facility in certain patients suffering from glycosuria and in disorders of nutrition allied to this disease. The suggestion naturally arises as to whether the ætiology of lichen planus and certain similar reactions of the skin may not also be associated with metabolic disorders of this type.

Pigmentary Changes.

Pigmentary changes in the skin have long been associated with our ideas of the health of the patient. The fact that a patient loses his normal colour and appearance is recognised as an indication that all is not well, and in clinical records it is frequently noted that a "sallow" or "earthy" appearance of the patient develops during the course of illness. The nature of the pigmentation producing the varieties of jaundice resulting from the staining of the tissues by the bile pigments is fairly well understood. We know that in addition to the true bile pigment the skin may also be coloured by other blood-derived pigments, such as urobilin. Still more recently it has been recognised that the tissues may be stained by pigments more remotely derived from the blood pigments in disease affecting the spleen, the liver, sometimes associated with glycosuria; we occasionally see examples of bronzed diabetes and of *hæmachromatosis* associated with certain types of splenomegaly. In addition, however, to these pigmentations, which are capable of explanation, there occur a series of disorders of pigmentation in which the colouring material is not derived directly from the blood pigment, but appears to be due to the formation of true melanin, the normal pigment of the body. A familiar example is the waxing and waning of pigmentation in certain parts of the body during pregnancy, the chloasma uterinum. But the most remarkable cases of increase of pigmentation occur in the course of Addison's disease. The newly deposited pigment is apparently true melanin, and its increase seems to be the direct result of disorder of the function of the suprarenal gland. It is known that pigmentation of exactly the same type may occur without the ordinary symptoms of Addison's disease. In a case under my own observation the patient, a young woman, suffered from great ascites, was severely ill with loss of weight and strength; the skin was widely pigmented, as in Addison's disease. The abdomen was opened, the abdominal fluid removed, and evidences of a mild, chronic peritonitis were observed. No opinion was formed as to the actual cause of the peritonitis. This patient, however, fortunately made an uninterrupted recovery and returned to her work as a school teacher, and remained under observation for some years. She gained strength, and at first gradually, then more rapidly, the abnormal pigmentation of the body vanished. It is very probable that some of the cases of leucomelanodermia which come under observation from time to time are associated with disease or disorder of the abdominal viscera in the neighbourhood of the suprarenal gland. It is interesting to recall that, just as in the case of xanthoma, in which there is reaction and overgrowth of tissue elements owing to irritation due to metabolic error, so in the case of these abnormal pigmentations the affected parts may react and increase in thickness owing to the formation of a certain amount of new tissue. The remarkable disease known as acanthosis nigricans, proved to be frequently associated with organic disease of abdominal viscera, appears to be an example of this sequence of events. With regard to this remarkable series of pigmentary diseases, the suggestion naturally arises in the mind, and is supported by a considerable body of clinical observation, that alterations in the distribution and amount of melanin pigmentation is directly associated with disorders or disease of the suprarenal gland and certain other glands producing "internal secretions."

Skin, Blood, and Lymphatic Glands.

In a review, however short, of the relationships we have been discussing, one cannot fail to refer to the change in the skin associated with disease affecting the structure of the blood and certain hitherto unknown affections of the lymphatic glands. The two conditions, lymphatic leukæmia on the one hand and the lymphogranulomatosis known as Hodgkin's disease, may be taken as examples. In both these conditions, differing so widely in many of their clinical symptoms, two sets of phenomena affect the skin. The skin in both may show tumours, lymphoid nodules in the case of leukæmia and lympho-granulomata in the case of Hodgkin's disease. In addition they both show remarkable cutaneous reactions without definite tumour formation. The skin may become erythematous and thickened, with symptoms of the most intense pruritus. There are few disorders of the skin so distressing as the pruriginous manifestations of both leukæmia and of Hodgkin's disease. They are, as is well known, frequently associated with characteristic fever. The evidence seems to point strongly in both cases to the infective origin of the classes of disease of which lymphatic leukæmia and Hodgkin's disease are examples.

A LOCAL SURVEY OF ENCEPHALITIS LETHARGICA,

BASED ON 32 CASES OCCURRING IN MANCHESTER DURING 1920.

BY W. ST. C. McCLURE, M.R.C.S., L.R.C.P., D.P.H.,
ASSISTANT TO THE MEDICAL OFFICER OF HEALTH, MANCHESTER.

IN view of the varying types of this disease which have been reported in different parts of the country, it seems desirable that some account of the incidence, distribution, and symptoms noted in a series of 32 cases occurring in Manchester during 1920 should be recorded.

The name encephalitis lethargica is apt to mislead, because, although lethargy is present in many cases, yet it is not an essential symptom, and it may be that, on account of the use of this term, cases occurring without lethargy have remained unrecognised, and have not, in consequence, been reported. During 1920 and in the early weeks of 1921, 39 cases, in which the date of onset of illness was in 1920, were reported to be suffering or suspected to be suffering from this disease. After investigation and observation 32 were accepted as true cases, some other diagnosis being subsequently arrived at in the other seven. Five of these seven cases ended fatally, and by post-mortem examination or by positive findings in the cerebro-spinal fluid the cause of death was found to be cerebral abscess, cerebral tumour, cerebral hæmorrhage, tubercular meningitis, and cerebral softening. The symptoms in the other two were accounted for by influenza. There remain 32 cases in which the diagnosis was accepted as correct.

The epidemiology and pathology of the disease are known to a limited extent only, and up to the present time no causal organism has been isolated. From analogy with similar diseases it seems likely that the illness is brought about by some infective microorganism. Nevertheless, there has not been in Manchester any spread of infection from one person to another, nor has any connexion between the cases been discovered.

Seasonal and Local Incidence of the Disease.

The cases were distributed over the year, according to the dates of onset as follows: first quarter, 2 cases; second quarter, 8; third quarter, 3; fourth quarter, 19. In the second quarter 2 cases occurred in April, 3 in May, and 3 in June; reported cases then became few until November, when there were 3, and in the month of December the prevalence reached its maximum, 16 cases coming to our notice.

The cases were widely distributed over the city and no connexion between them was traced, although careful inquiry was made. The following figures show the incidence on the various districts: Ancoats, 2 cases; Central, 1; *Cheetham*, 3; *Crumpsall*, 3; *Newton*, 1; Clayton, 1; Ardwick, 1; Openshaw, 1; West Gorton, 3; Rusholme, 1; Chorlton-on-Medlock, 2; Moss Side, 2; Withington, 4; Gorton, 3; Levenshulme, 4. If the three divisions of the city be taken, 3 cases occurred in Manchester township, 8 in North Manchester, and 21 in South Manchester, the incidence rates being 0·30, 0·34, and 0·45 per 10,000 of the several populations. The 16 cases in which the onset of the illness was in December occurred in 12 different districts.

Infectivity.

The disease has shown no signs of infectivity—that is to say, no connexion has been traced between the cases which were widespread over the city, nor did infection spread to any of 138 family contacts. No common source of infection was found. As regards the milk-supply, for instance, of the 32 persons affected four habitually consumed condensed milk, and the remainder obtained their milk from 28 different sources; nor does transference by means of other foods seem likely, though our investigation in this direction is incomplete. Housewives and workers have been attacked in about equal numbers, scholars and infants have not escaped. It is certain that cases of encephalitis lethargica occur which remain unrecognised and escape investigation, and so connecting links may be missed. Nevertheless, the conclusion may be deduced either that the disease is not infectious or that the infective material is widespread, and that there exists amongst the majority of people a natural immunity to it.

Cases of poliomyelitis and of cerebro-spinal fever crop up from time to time in a similar manner. These two diseases are known to be due to infective micro-organisms, but no satisfactory explanation of their mode of spread is forthcoming. It appears that they may occur sporadically, or may, under certain unknown circumstances, assume epidemic form. Until our knowledge becomes more complete encephalitis lethargica should be presumed to be infectious or contagious and precautions taken accordingly.

Age- and Sex-Incidence.

Table I. gives the age-groups and the sex of those attacked and of those whose illness proved fatal. It will be noted that males and females were about equally affected and that adults were attacked rather than children.

TABLE I.

Age-groups.	Cases. M.	Cases. F.	Deaths. M.	Deaths. F.	Total cases.	Total deaths.
Under 10 years	2	3	2	3	5	5
10 to 19 „	7	4	2	2	11	4
20 „ 29 „	2	2	1	0	4	1
30 „ 39 „	1	2	1	1	3	2
40 „ 49 „	1	4	1	2	5	3
50 „ 59 „	3	1	2	0	4	2
			Total ...	...	32	17

The question whether this disease is the same as, or a variant form of, poliomyelitis has been studied by a number of workers, and the conclusion arrived at on the evidence so far obtained is that encephalitis lethargica is a distinct entity. The data in the Manchester series as regards seasonal incidence, age of attack, and clinical manifestations tend to confirm this conclusion, but the number of cases dealt with is small and reliable inferences cannot safely be drawn. During the year only 6 cases of poliomyelitis were reported, 1 in July, 2 in August, 1 in September, and 2 in October. The entire absence of reported cases of poliomyelitis in November and December, when encephalitis lethargica reached its maximum prevalence, is a point to be noticed.

Occupational and Class Incidence.

Of the 32 patients 4 were infants, 4 scholars, 10 were women engaged in housework, and 14 were adults employed, each in a different occupation. There is nothing to be learned, therefore, by further analysis. The social status of those attacked may be gathered from a consideration of the size of house occupied by them, and by the presence or absence of overcrowding. The figures are given in Table II.

TABLE II.

Houses with—	No. of cases.	Number of houses with— 1 person or less per room.	Number of houses with— More than 1 but less than 2 per room.	Number of houses with— 2 or more per room.
4 rooms	12	4	7	1
5 „	3	3	0	0
6 „	11	8	3	0
7 „	2	2	0	0
8 „	4	4	0	0

The greater number of cases occurred in houses with n average of one person or less per room, and the idence is fairly well spread over the various social des.

Symptoms.

It is only by the collection and study of the symptoms esented by a large number of cases that any reliable classification can be made. The symptoms found in the 32 cases under consideration and their relative frequency are therefore recorded here without much attempt to draw any general inferences.

General symptoms.—Most, but not all, began with symptoms of an acute infection, fever, headache, vomiting, pains in the body and limbs. Fever was not constant, and when present the temperature rarely exceeded 103° F., more commonly it ranged between 100° and 102°. In 11 cases it was absent altogether. This may be because the cases were not seen early enough but, in any event, the rise in temperature was, in many, a brief incident at the commencement of the illness. The absence of temperature is not necessarily of good portent; of the 11 cases in which it was absent, 6 died, 3 recovered, and 2 are yet ill. Headache was complained of by 16 patients, and 11 began with vomiting. Both headache and vomiting disappeared within a few days as a rule. In a few, headache was persistent throughout and in one case in which the diagnosis is still in doubt, vomiting has continued for several weeks. Pain in the limbs and body occurred in about half the cases as an initial symptom, and in rather less than this number pains of a more localised character, and probably nervous in origin, have been a marked feature in the later phases of the illness. General asthenia, becoming more pronounced as the disease progressed, but without any marked wasting, occurred in all our cases.

Duration of symptoms of onset.—The period elapsing between the appearance of the first symptom and the onset of prostration can be stated approximately as follows: 1 to 3 days—14 cases; 4 to 7 days—8 cases; 8 to 14 days—7 cases; 15 to 24 days—3 cases. It is not, therefore, generally speaking, a disease of sudden onset, as is the case with cerebro-spinal fever, and as a rule with poliomyelitis.

Nervous symptoms.—Lethargy, which became extreme at some stage of the illness, was a prominent symptom in 29 cases. In the remaining 3, although there was some hebetude of body, there was no inclination to sleep.

Paralyses.—Fifteen cases were associated with cranial nerve paralysis, and, in addition, 5 others complained of diplopia at some time during their illness. There were also cases in which the muscles of the face were relaxed and expressionless, due apparently to general asthenia. The various nerves were involved as follows: third, 4 cases; third and sixth, 2 cases; sixth, 1 case; sixth and seventh, 2 cases; seventh, 4 cases; seventh and ninth, 1 case; and possibly the fifth in 1 case. Paralysis of the third nerves was seldom complete. Squint or diplopia occurred in 13 cases, or in rather less than half of the total. Nystagmus of a coarse kind was present in 3 cases. The condition of the pupils and the pupillary reactions were found to vary at different stages of the illness, and gave no aid to diagnosis. The fundus oculi was examined in 17 cases and was unchanged in 11; the retinal veins were congested in 4, and in 2 there were signs of commencing optic neuritis.

Limb paralyses.—In no instance was there paralysis of the limbs, but in 2 cases the left arm was found weaker than the right, and in 1 case there was temporary paresis of the arm and leg on one side.

Positive nervous symptoms.—These symptoms did not predominate in our series. Convulsions ushered in the illness in 2 instances, bilateral twitchings of the lower face muscles occurred in 2, of the jaw muscles in 1, of a group of muscles in the upper arm in 3, and spasms of both arms in 1 case. Persistent headache or pains in some part of the body, usually the shoulders or back, were recorded in 8 cases.

Other symptoms and signs.—Hiccough was the initial symptom in 2 cases; buzzing in the ear was the first sign of illness in 1. Swelling and redness of one side of the face was noticed twice, and swelling of one leg once. Bowels were commonly constipated. Incontinence of urine was noted in 7 cases and retention in 3: paralysis of the sphincter ani was present in 5 cases. Skin eruption was seen only in 1 case, and in that instance it was of an acneiform character on the back.

The condition of certain reflexes was recorded in 29 cases as follows:—Patellar reflexes: about normal 10, increased 2, absent 8. Plantar reflex: normal 16, extensor response 2, absent 2. Ankle clonus: present in 1. Kernig's sign: present in 5.

Results of Illness.

Of the 32 cases, 17, or about 53 per cent., proved fatal. The duration of illness in the fatal cases was as follows: Under 1 week, 5 cases; 1 to 2 weeks, 4 cases; 2 to 3 weeks, 2 cases: over 3 weeks, 6 cases. One was ill for 170 days, one for 74, and one for 57 days. Of the remaining 15 cases, 2 made a complete recovery, 7 have been ill for a few weeks and are still ill. The condition of the other 6 may be stated briefly:—

CASE 7.—M., 50. Condition nine months after onset: Face expressionless; head and shoulders bowed, limbs stiff, shuffling gait.

CASE 8.—F., 20. Condition nine months after onset: Mental depression, head and shoulders bowed, arms bent, stiff, and "sticky," paresis left shoulder muscles.

CASE 15.—F., 45. Condition three months after onset: General asthenia, paresis right arm and forearm.

CASE 17.—M., 22. Condition two months after onset: General asthenia, mental dullness, right partial ptosis.

CASE 24.—F., 42. Condition two months after onset: General asthenia, paresis right forearm.

CASE 32.—M., 17. Condition nine weeks after onset: General asthenia, mental dullness, and noises in ear.

Pathological Examinations.

The blood of two patients was examined for Wassermann reaction, with a negative result in one and a doubtful result in the other. Cerebro-spinal fluid was examined from 12 patients. In all it was clear; in one *Staphylococcus aureus* was said to be present; in the remainder no organisms were found. In one instance there were 159 lymphocytes per c.mm., in another 30. In the remainder there were either no cells or very few.

Post-mortem Examinations.

In two cases a post-mortem examination was made.

CASE A.—M., 28. Onset of illness, May 24th, 1920; date of death, June 10th. Illness began with hiccough, followed by headache and drowsiness progressing to extreme lethargy. Ptosis and left internal strabismus were present.

The following is a copy of a report upon the examination of the brain by Dr. G. D. Dawson, a worker in Professor S. Delépine's laboratory. The brain was sent for examination by Dr. T. E. Dickinson, acting superintendent of Monsall Hospital:—

"A brain, weight 1315 grammes, shape normal. There is general congestion of superficial blood-vessels. No evidence of meningitis. On section, the grey and white matter everywhere showed numerous small, dilated blood-vessels, the congestion is most pronounced in the pons and perhaps in the occipital lobes. No hæmorrhages or other lesions are visible to the naked eye. The ventricles are of normal size and do not contain any excess of fluid."

Microscopical Examination.

A. *Transverse section through middle of pons.*—"There is no evidence of meningitis. The most noticeable feature is the presence, especially in the grey matter, of numerous congested blood-vessels, mostly of small size. In most cases the perivascular spaces are distinctly enlarged: some are filled with small round cells, others contain a few extravasated red cells. Some hæmorrhages are present, but they are small and few. There is no clear evidence of any considerable degree of chromatolysis."

B. *Section through part of left occipital lobe.*—"The appearances are similar to those of section A, but less pronounced."

CASE B.—Male, 39 years; onset of illness, Nov. 14th, 1920, date of death, Jan. 26th, 1921. The illness began with pains in the "stomach" and vomiting. No headache, but pains in shoulders and back. Three weeks later there were diplopia and blurring of vision; ptosis of the left eyelid and left internal strabismus subsequently developed. There was little or no lethargy, but progressive asthenia ended in death.

A post-mortem examination was made. There was no evidence of meningitis, no deformity, no adhesions or thickening of the membranes. On section, no gross lesions were seen, though the posterior half of the brain was decidedly congested. The microscopical examination has not yet been completed.

I am indebted to those medical practitioners who allowed me to see their patients.

A CASE OF OSTEITIS DEFORMANS.

BY DOROTHY C. HARE, C.B.E., M.D. LOND., M.R.C.P. LOND.,

ASSISTANT PHYSICIAN, ELIZABETH GARRETT ANDERSON HOSPITAL.

With X Ray Report

BY C. C. BERNARD, M.A., L.M.S.S.A.,

HONORARY RADIOLOGIST TO THE ABOVE HOSPITAL.

THE patient, an unmarried woman, aged 47, is a native of Rangoon. Her mother was Armenian, her father Eurasian; she was healthy, though not robust, as a child and young woman. At the age of 26 she had both ovaries removed for uterine fibroid at Madras Maternity Hospital by Sir Arthur Branfoot, after which she is said to have had fair health; but between the ages of 30 and 40 she had attacks of "kidney trouble" and recurrent fever diagnosed as malaria. At about the age of 42 she was told that her mitral valve was affected. The present affection of the bones was first noticed about June, 1917, when a nurse, who was massaging the patient, discovered that her right humerus and right femur were bent. The patient at this time complained of pains in the back, ribs, and ankles, and of general tenderness in the limbs. She went to the General Hospital, Madras, in October, 1917, where the disease was diagnosed as osteo-malacia. She was treated with calcium lactate, and during the next few months the pains and tenderness lessened, and have never returned so acutely since. She has, however, complained increasingly of pain in the lower part of the spine, relieved by lying down. She has been unable to walk far and is easily tired by exertion.

The patient's height has diminished progressively, and she is said to have lost at least 7 inches. The only written record is that in 1918 she measured 4 ft. 9 in. in her stockings; her present height is 4 ft. 7 in. The weight does not seem to have varied much, being 102 lb. in January, 1918, and 93 lb. in July, 1920. The head has gradually enlarged; the patient says that the increase in size was first noticed by her friends in the latter part of 1917, and that in 1919 it measured 23⅜ in. in circumference; the present measurement is 24½ in. During 1918 there was a return of kidney trouble, and small quantities of blood and pus were passed in the urine, which contained at times a red sediment. The patient says that she has suffered frequently from intestinal flatulence, but on the whole her general health has remained good.

Dietetic Habits.

Full notes on the patient's customary diet are recorded in view of the possibility that this disease may one day be brought into line with other bone diseases due to food deficiencies. The patient has always had plenty of eggs and milk. She is fond of meat and usually eats it twice a day. She has never eaten much vegetable, and would go for weeks without taking green vegetables, roots, or potatoes; but she has always eaten some fruit daily, such as mangoes, mangosteens, bananas, or plantains; apples, pears, or grapes have been eaten occasionally. She eats very little bread and does not care for sugar or sweets. She never takes meat fat, and very little butter; bacon has only been eaten recently. The patient has always been careful of her diet on account of indigestion, but made no alteration in her habits of diet before the onset of this illness. She suffered no shortage of any particular article of diet during the war.

Previous Treatments.

From October, 1917, for about six months the patient was treated with large doses of calcium lactate, 30 to 40 gr. daily. After that time the drug was stopped, as it was thought to be causing indigestion, but it has been taken at irregular intervals since. The tenderness of the bones disappeared whilst taking the drug. During 1918 the patient was given pituitary extract in tablet form, 2 gr. daily for about three months, but it was not taken with great regularity. The patient noticed no effects. The kidney symptoms were treated with an autogenous vaccine of a coliform bacillus from November, 1919. Three series of ten injections each have been given. In March, 1920, the patient was recommended to come to England to see Dr. Louisa Hamilton, and was admitted to the Elizabeth Garrett Anderson Hospital on June 26th, 1920.

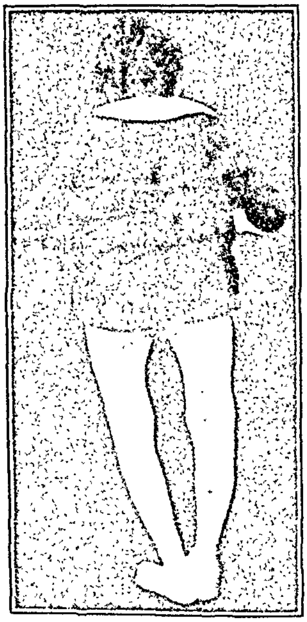
General Appearance.

The patient is a small woman, height 4 ft. 7 in., of a sallow, dark complexion; she is thin, with very poor muscular development, but not wasted. She walks with a stick, moving slowly and with caution, carrying the trunk forward and the head well in advance of the rest of the body. The back is bent and the legs bowed. The neck appears to be short, as the chin is bent down on the chest. The large size of the forehead immediately attracts attention. The expression of the face is intelligent and mobile. In conversation the patient shows a normal mentality, though she is emotional and nervous.

Skeleton.

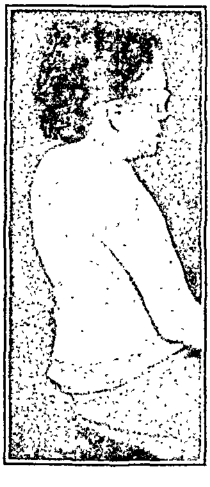
Skull.—The cranium is enlarged and the forehead high and broad. The face bones are normal in appearance, but small in comparison with the size of the cranium. Teeth good.

FIG. 1.



Showing bowing of the legs.

FIG. 2.



Showing position of head, shortening of neck, and curvature of spine and right humerus.

Measurements.—Horizontal circumference at level of temporal fossæ, 24½ in.; circumference at level of occipital spine and frontal prominence, 24½ in.; antero-posterior circumference between same points, 15 in.; antero-posterior diameter between occipital spine and base of nasal bones, 7¼ in.; maximum transverse diameter between mastoid processes, 7⅝ in.

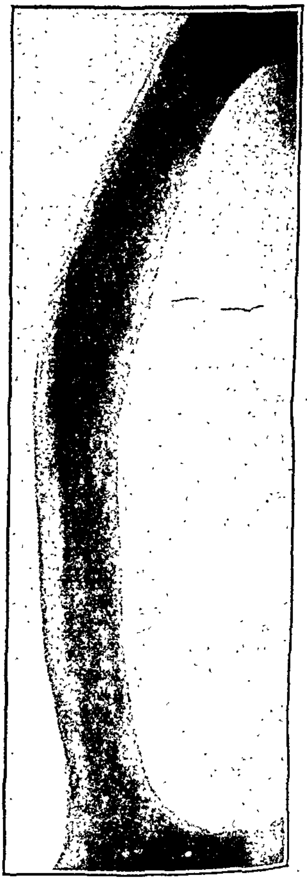
Trunk.—The spine has a double antero-posterior curvature, with an exaggerated convexity backwards in the upper dorsal region and forwards in the lumbar region: thorax correspondingly flattened in front and abdomen short and wide; right clavicle thickened and the natural curves increased; pelvis slightly flattened and sacrum pushed forward.

Limbs.—Right humerus bent forwards and slightly outwards and thickened: left humerus shows a very slightly increased curve. No change detected in bones of forearms or wrists: in right hand first and third metacarpal bones are thickened and convex dorsally: other bones of the hands unchanged. Both *femora* show changes, being bent outwards and forwards and moderately thickened. No apparent alteration of the angle of neck and shaft. Measurement (with the patient in horizontal position) from tip of great trochanter to the vertical line from anterior iliac spine is 2½ in. Tibiæ bowed forwards and thickened. When patient stands with ankles touching, the knees are widely separated. Feet show no deformity; joints are unaffected and movements free.

Other Systems.

Circulatory system.—No evidence of thickening of the arteries; heart shows no enlargement and is regular in force and frequency. At apex the first sound is short, and there is a systolic murmur conducted outwards. At base a loud rough systolic bruit most marked in the pulmonary area. *Digestive system.*—As stated above, the patient has always been liable to flatulence, otherwise there is no abnormality. *Urinary system.*—No enlargement of kidneys can be detected; urine has always been normal while the patient has been under observation. *Blood.*—No anæmia. Wassermann test negative. *Nervous system.*—No abnormality noted.

FIG. 3.

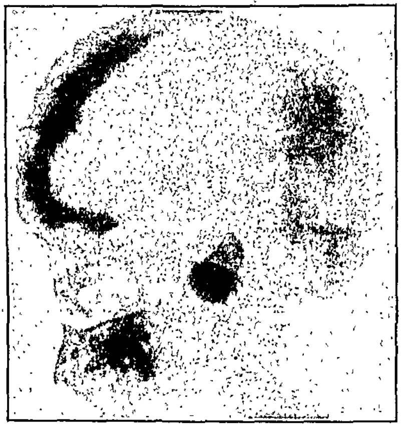


The right humerus.

Discussion.

The diagnosis in this case is of interest. Clinically the changes observed are fairly in accordance with those of Sir James Paget's[1] classical description, on which the differentiation of the disease as a clinical entity was first established. The insidious onset, chronic course, and relatively slight disturbance of general health, the conspicuous bending and thickening of the bones, tendency to symmetry in the changes, absence of arthritis, and above all the progressive enlargement of the cranial bones make up a diagnostic picture. The X ray examination of the skeleton, however, confirms the diagnosis and is in agreement with the reports of recent cases. Locke[2] and R. Abbe[3] both publish accounts in which X ray photographs of the skull are printed, and lay stress on the enormous thickening of the frontal, parietal, and occipital bones, with an indefinite woolly outline to the shadow. The first writer remarks that this thickening may be disclosed by X ray examination when the head is not apparently greatly enlarged. Abbé considers that the X ray of the skull may in some cases be the only means of establishing the diagnosis. The differential diagnosis from osteo-malacia, however, rests not only on this condition of the skull, but on the changes in the long bones. In osteitis deformans the shafts of the long bones are gradually thickened and uniformly curved, whereas in osteo-malacia they are thin and atrophied and yield with an angular bend. No doubt at the beginning of this patient's illness the clinical diagnosis might have offered some difficulty, but by X ray examination the two conditions should be distinguishable even in the early stages. In a recent report on osteo-malacia and late rickets by Professor E. Looser,[4] of Vienna, the writer states that in osteo-malacia X rays show bony changes even in cases of moderate severity, and that in slight cases thinning of the wall of the shaft of the long bones is seen, and is especially plainly demonstrated in the hand. He publishes plates to confirm this. In contrast to these the radiogram of the hand printed herewith is interesting, showing as it does the dense thickening of two metacarpals, in an otherwise normal picture. Late rickets, according to the same authority, cannot be distinguished clinically from osteo-malacia, the differences lying in the age and rapidity of onset. Late rickets usually appears in adolescence, and osteo-malacia in young adults. The X ray appearances of these two diseases are indistinguishable. From these considerations there seems to be little doubt that the diagnosis in this case is osteitis deformans. The nature of the disease is still unknown, and its causes hardly even conjectured. The possibility of it being a syphilitic affection has been discussed by those qualified to give an opinion, and has been dismissed as unproven and improbable. The Wassermann reaction in this patient is negative. Other chronic infective conditions, deficiencies of diet, and disorders of internal secretions are all known as causes of bone diseases, but there is at present no certain knowledge of the causative factor in osteitis deformans.

FIG. 4.



The skull.

I am indebted to Dr. Louisa Hamilton for permission to publish this case, and to Dr. C. C. Bernard for her coöperation.

X Ray Report.

The skeleton shows changes typical of osteitis deformans; these changes are most marked in the skull, the right humerus, the femora, and the lumbar vertebræ and the pelvis. The appearances of the bones are as follows:—

Skull.—The whole calvarium is much thickened in the frontal region to over 1½ inches. There are variations in the density of the bone, causing a mottled appearance, and a woolly outline. (See Fig. 4.)

Right clavicle.—The bone is about double the thickness of the left clavicle, and the normal curves are exaggerated.

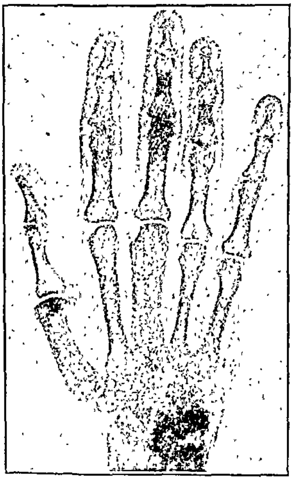
Spine.—The lower three lumbar vertebræ have an irregular outline; the bone is increased in density and the normal structure is gone. The same changes are marked in the sacrum. The other vertebræ do not appear to be much affected.

Pelvis.—All the bones are thickened. The changes in the minute structure are most marked in the ischia and pubes.

Right humerus.—The whole bone is much thickened and is curved forwards. The medullary cavity is invisible, and the normal structure is completely gone except in the two condyles. (See Fig. 3.)

Right hand.—The third metacarpal is about twice the normal diameter; the first metacarpal is thickened in a less degree. There is no differentiation between the cortex and the medulla, and the minute structure is abnormal. All the other bones of the hands are unaffected. (See Fig. 5.)

FIG. 5.



The right hand.

Right femur.—The lower third of the shaft is much thickened, the upper third somewhat, the cortex and medulla being visible in the middle third only. There is a slight outward curve.

Right tibia.—The bone is thickened, the medullary cavity obliterated, and the minute structure abnormal. There is a curve forwards.

Left femur.—The bone is curved forwards, this being most marked in the lower third, where the bend appears to form a wide angle. The upper and lower thirds are much thickened with obliteration of the medullary cavity.

Left tibia.—There is a slight forward curve, and marked thickening in the upper and lower thirds. In the middle third there is some thickening of the cortex, and though the medullary cavity is present, it would appear to be in an early stage of the disease.

No changes are detected in the bones of the face, left clavicle, ribs, left upper limb, right forearm, fibulæ, and feet. There are also no changes in the bones entering into the joints. There is no evidence of calcification of the arteries. In the abdomen there is a shadow, probably due to renal calculus.

AURICULAR FIBRILLATION:

SOME OBSERVATIONS AND DEDUCTIONS FROM A SERIES OF 400 CASES.

BY D. S. BRACHMAN, M.R.C.S., L.R.C.P. LOND., B.A., M.D. PHILA.,

ASSISTANT MEDICAL OFFICER, ROYAL CHEST HOSPITAL DISPENSARY; LATE RESIDENT MEDICAL OFFICER, NATIONAL HOSPITAL FOR DISEASES OF THE HEART.

OF all conditions treated at this hospital that of auricular fibrillation forms one of the most important, if not the most important group. It is found in no less than 25 per cent. of all patients admitted to the wards,[1] yet approximately 8 cases out of 10 are not fully recognised as such prior to admission, whereas even without polygraphic or electrographic help not more than 1 out of 10 should be missed.

The following observations are based on 400 cases of this condition, 110 of which were in-patients and 290 out-patients. The youngest was 16 years of age and the oldest 76.

In auricular fibrillation there is a lack of coördinate muscle contraction, and in its place individual fibres or groups of fibres contract incoördinately. Some of these individual stimuli are transmitted through the bundle system, and accordingly the ventricles contract unequally and irregularly and usually with increased rate. This is manifested not only in the complete irregularity of the heart, but also in the complete irregularity of the pulse. This irregular irregularity is the most important sign we have, and is almost pathognomonic of auricular fibrillation. The force of the individual beats varies, and it is usually found that some of the ventricle beats do not reach the wrist, hence it is necessary to take the heart-rate at the apex as well as the pulse, the latter being an index as to the number of efficient ventricle contractions. The greater the difference between the apex- and pulse-rates, the greater the number of inefficient beats, tending to ventricular exhaustion.

Differential Diagnosis.

There are two other conditions giving rise to an irregularly irregular pulse and which must be differentiated from auricular fibrillation, viz.: 1. Multiple premature beats, especially when auricular in origin. 2. Sino-auricular heart-block. In most cases of premature beats of ventricular origin there is an underlying regular rhythm, the contractions of which are practically always of equal force, recognised by continued auscultation at the apex, the premature beat usually being followed by a comparatively long pause. Frequently in these cases slight exercise will eliminate the premature beats, or at least sufficiently so for diagnosis, while in auricular fibrillation exercise almost invariably accentuates the irregularity. Rarely is it necessary to resort to polygraphic or electrocardiographic means for differentiation. In auricular premature beats, a rather infrequent condition, the diagnosis is made certain only by an electrocardiogram or polygram. Clinically, however, auricular premature beats may precede the onset of auricular fibrillation. Sino-auricular heart-block, on the other hand, is usually associated with an approximately normal or somewhat lower heart-rate, while in auricular fibrillation the rate is more often very rapid. Also in sino-auricular block the apex- and pulse-rates are the same, and there are long pauses in which the heart is completely silent. Sino-auricular block can be definitely differentiated from a slow fibrillation only by the electrocardiogram or polygram. It is, however, a comparatively rare condition. Another common irregularity, which ought not, however, to be confused with auricular fibrillation, is sinus arrhythmia. This is a regular irregularity in which the heart-rate usually increases during inspiration and decreases in expiration. This condition is very easily differentiated if watched for, and is frequently found in children.

Investigation of Pathological Condition.

Having diagnosed auricular fibrillation, the two essential points to consider are: (1) the pathological condition of the heart which led to auricular fibrillation; (2) the effect that fibrillation of the auricles will have on the circulation as a whole, and particularly on the left ventricle.

Post-mortem examination shows that there is almost always definite myocardial change, usually fibrosis in the wall of the auricles, interfering with the normal activity of those chambers. Furthermore, one has to determine (*a*) whether this myocardial change is confined to the auricles, or (*b*) whether the ventricles also are affected. Naturally, if the ventricles are involved, especially the left ventricle, the onset of fibrillation is a much more serious matter, because it is the left ventricle that is mainly responsible for the circulation.

In mitral stenosis there is very little doubt but that the left auricle is greatly handicapped, being possibly the only part of the heart muscle affected. There is usually dilatation and hypertrophy followed by muscle failure, ending in degeneration. The degenerated muscle becomes hyper-irritable.[2] When the irritability of the various groups of auricular fibres becomes greater than at the normal pace-maker, auricular fibrillation sets in. Occasionally there is a localised myocardial involvement of the auricles secondary to pericarditis, or, as is even more unusual, auricular damage alone may remain following a general infection.

After the onset of auricular fibrillation the ventricle-rate is a matter of great importance, for the more rapid the rate the more will it tend to produce myocardial exhaustion. The ventricular rate may be greatly influenced by emotion. This is shown clinically by the fact that the practical normal heart-rate of a patient fully under the influence of digitalis may be greatly increased by excitement or fright. The ventricular rate is also increased by exertion, and usually out of proportion to the amount of exertion, especially when there is marked muscle involvement of ventricle. If one compares the effect of emotion and exercise on the ventricular rate, one frequently finds that the heart-rate may go up much higher on slight excitement than after exertion—e.g., in one case a patient without continuous fibrillation was easily made to fibrillate by the breaking of an electric bulb or by the loud slamming of a door, but would not fibrillate on walking up five flights of stairs. Another patient, on the other hand, was easily made to fibrillate by either excitement or exertion, but would soon return to the normal rhythm.

Treatment.

The main object to be achieved when treating auricular fibrillation is to get the heart-rate at the level where it produces an adequate circulation without undue ventricular work, which is usually between 65 and 80 a minute. This is best produced by giving digitalis in sufficiently large doses to bring the heart-rate down to approximately 50 beats a minute, when the drug is stopped. The digitalis is then again started, but in a smaller dose, and gradually increased until the desired rate is procured. The resulting dose is continued indefinitely, with changes only as varied circumstances may require. Occasionally it is desirable to keep the rate nearer to 90 a minute, but here the prognosis is worse.

The great therapeutic agent in auricular fibrillation, therefore, is physical, mental, and cardiac rest. Cardiac rest is produced by the digitalis group, resulting in partial paralysis of the bundle of His, less impulses being transmitted to the ventricles. Associated conditions and symptoms, as hyperchlorhydria with wind in stomach, must also be dealt with.

---

[1] Patients considered suitable for admission include those suffering from acute valvular disease, chronic valvular disease, myocardial disease, advanced arterio-sclerosis, including secondary kidney involvement, advanced Graves's disease with myocardial involvement, acute infective endocarditis, aneurysm, &c.

[2] The normal cardiac contraction starts at the sino-auricular node at the most irritable area.

Analysis of Cases.

Turning to the actual detailed analysis of the 400 cases of auricular fibrillation, we shall consider: (1) Ætiology: (*a*) age- and sex-incidence, (*b*) pre-existing disease; (2) symptoms, relative frequency; (3) associated conditions; (4) X ray appearances, measurements.

1. *Ætiology*.—(*a*) Age and sex incidence. Of the 400 patients with auricular fibrillation examined 220 were males and 180 females, in the proportion, therefore, of 11 males to 9 females. From this it is apparent that one sex cannot be considered very much more susceptible to this condition than the other sex. Going into the ages of these patients, 265 of the 400 cases, or 66 per cent., occurred *after 40 years*, the largest number 112, or 28 per cent. of the total, occurring between 41 and 50 years. (See Table I.) (*b*) Pre-existing disease. Rheumatic fever is by far the commonest antecedent disease in auricular fibrillation, being found in no less than 123 (8 of which also had chorea), or 35 per cent. of the 348 cases in Table II. If to this we add the 14 cases of chorea alone, the cause of which is strongly affiliated with that of rheumatic fever, we have 39 per cent. of the total. On the other hand, there was a history of no previous illness in 66, or 19 per cent. of the total, a very appreciable factor and a distinctly important point in the matter of causation. Of the 46 cases giving a history of influenza, the actual cause is debatable, the severe forms of influenza being, however, of definite importance in cases with heart strain or where the heart muscle has been previously affected. Scarlet fever is not an uncommon disease in childhood; it is doubtful whether it is a cause of cardiac disease. A prominent observation in this series is that Graves's disease was found in ten cases, all of which were myocardial only.[3] The Wassermann reaction was taken in only definitely suspected cases and not as a routine, there being seven positive, in five of which the myocardium alone was involved. Apart from the subject of auricular fibrillation Table II. shows two outstanding facts which might usefully here be mentioned: (*a*) Rheumatic fever is much more likely to involve valves or valves and myocardium—such being the case in 109 out of 123 patients—than myocardium alone; (*b*) of the 14 cases of chorea (without rheumatic fever) all involved valves. In no case was the myocardium alone affected.

TABLE I.—*Age and Sex.*

—	Sex.	Age. 16-20	21-30	31-40	41-50	51-60	61-70	71-76	Total.
Out-patients	M.	3	30	34	42	41	12	0	162

Total ...	...	8	69	88	112	95	23	5	400

2. *Symptoms, relative frequency*.—There are no symptoms pathognomonic of auricular fibrillation, nor are there any that are much more suggestive of this than of other cardiac conditions. In the 400 cases used in this series (all in-patients) there were no leading questions asked, and the symptoms are those given by the patients practically unaided. It is very apparent here (Table III.) that the commonest symptom in heart failure is dyspnœa and that this symptom is found as often when fibrillation is absent as in its presence. The next two symptoms commonly met with are pain (under or across the heart) and palpitation. Pain is somewhat more common in the absence of fibrillation, while palpitation is found somewhat more often in fibrillation cases. Among the less usual symptoms, cough is twice as common, and insomnia four times as many fibrillation as in non-fibrillation cases. While nervousness is objectively common, it is but seldom complained of as a symptom. Subjective feeling of irregular beating of the heart has been mentioned as a common symptom, but in this series, shown in Table III., it is comparatively rare.

(2)	183	106	70	48	13	21	4	3	15	2	3

(1) = 200 cases of fibrillation.
(2) = 200 cases without fibrillation.

3. *Associated conditions*.—Of 359 cases: (*a*) 133, or approximately 37 per cent., had definite mitral stenosis; (*b*) 132, or approximately 37 per cent., appeared to be primary myocardial; (*c*) 65, or 18 per cent., had mitral regurgitation; (*d*) 24, or 6·7 per cent., had both mitral and aortic involvement; (*e*) 5, or 1·4 per cent. had aortic involvement only, including 2 cases with double aortic. From this one would infer that myocardial involvement alone is found associated with auricular fibrillation practically as frequently as pure mitral stenosis, although some authorities have stated that mitral stenosis is associated with most cases. If, however, we add the mitral and aortic cases having mitral stenosis, of which there were 10 out of 24, we have 143 mitral stenosis cases as against 132 myocardial, or only 8½ per cent. more in a total of 359 cases. Aortic disease alone accompanied auricular fibrillation in only 5 cases and is therefore comparatively unusual, while both mitral and aortic involvement occurred in 24 cases, or 6·7 per cent., of the total. (Table IV.) Group (*c*) consists of patients having only a distinct blowing systolic murmur at the apex transmitted to the axilla. Since most patients with auricular fibrillation are first seen at the hospital after fibrillation has commenced, there is no certain way of recognising those cases which showed a presystolic murmur before

[3] "The Heart in Graves's Disease," by J. Strickland Goodall, Practitioner, July, 1920.

the onset of this change of rhythm.[4] If the second pulmonary sound is reduplicated or markedly accentuated and the electrocardiogram shows a right-sided preponderance, mitral stenosis is more likely to be present. A diastolic murmur at the apex not of aortic or exocardial origin is, of course, sufficient to diagnose stenosis. Also, considering the very large size of the heart in auricular fibrillation, especially of the auricles, it is apparent that some of the mitral regurgitation murmurs, in spite of all the signs of what is considered an organic lesion, are due to relative mitral regurgitation, as was the case in a recent post-mortem examination at this hospital. These cases would accordingly come under the heading of those associated with myocardial diseases.

4. *X ray appearances; measurements.*—All patients coming to this hospital are X rayed as part of the routine examination. With the tube 6 ft. away from the object the rays are practically parallel, and the image is then the same size as the object. For convenience in actual practice, however, it is desirable to place the tube very much closer to the patient and to allow for the distortion, and as used at this hospital the image on the screen is ¼ in. to ½ in. larger than the actual size of the heart. The size of the normal heart varies with age, sex, mode of life, &c., of the individual. Working on healthy hearts of young men under 30, Strickland Goodall showed that the average of the transverse diameters in a series of cases was 5¼ in., and this figure is taken as a standard in Table V.

TABLE V.—*Transverse Diameter of Heart.*

Fibrillation.	Without fibrillation.
One case with diameter to 5⅜ in.	33%
16% with diameter of 5⅛ to 6 in.	26%
42% „ „ 6⅛ to 7 in.	26%
24% „ „ 7⅛ to 8 in.	11%
16% „ „ 8⅛ to 9 in.	2%

The sign most commonly found in auricular fibrillation, next to irregular irregular rhythm, is enlarged heart, particularly the auricles being so. In the 117 cases detailed here, where the percussion figures were corroborated by X ray, and in which the actual measurements are given, only one heart showed a diameter of 5⅜ in. or less. Therefore in practically every case the diameter of the heart was above the normal limit. Over 80 per cent. of the fibrillation cases showed a heart diameter of 6 in. or more, as against 40 per cent. in non-fibrillation cases, while 40 per cent. showed 7⅛ in. or more, as against 13 per cent. in non-fibrillation cases. When in auricular fibrillation the heart is beating rapidly the apex-rate as a rule differs from the pulse-rate, and it is necessary to count both. (This is, therefore, a third sign to be looked for.) Since the apex gives the actual ventricle-rate, while the radial pulse gives only the rate of those beats that are sufficiently powerful to force the blood through the body, a rapid apex-rate leads to earlier ventricular exhaustion. This sign is of great importance in prognosis. As a general rule the greater the difference between the apex-rate and the pulse-rate, especially after exercise or emotion, the worse the prognosis.

The three signs of auricular fibrillation to be emphasised are thus: (1) Complete irregularity of the heart. (2) Increase of the cardiac diameter. (3) A difference in apex- and pulse-rate.

Prognosis.

Paroxysmal attacks of tachycardia occasionally prove to be attacks of auricular fibrillation, and may last only a few minutes to several days and then return to normal. There may be but one such attack in the patient's life, or there may be several, or, as is most usual, once fibrillation starts it continues the rest of the patient's life. If the ventricle, particularly the myocardium, is in good condition, and the rate has been kept down sufficiently to avoid exhausting it (at or near 70), whether by nature, rest, or digitalis, the auricles will continue to fibrillate until they become completely exhausted. The auricle waves in the electrocardiogram then become very small and fine, and ultimately disappear almost entirely. In other words, the auricles now become passive chambers and take very little active part in the cardiac cycle.[5] The ventricles, however, may continue to receive the impulses from the auricles through the bundle of His. Sometimes it is necessary to use a continuous drum over a comparatively long time before any auricle waves can be found. This condition is differentiated from a complete heart-block in that (*a*) the waves in the auricles will be found, if carefully looked for, usually as fine waves, however, while in a true complete heart-block practically normal P waves are present; (*b*) the rhythm of the heart continues irregularly irregular, while in a complete heart-block the ventricle usually takes on a regular rhythm; (*c*) the rate is usually higher than in the heart-block. It is thus apparent that the impulse starts in the sinus or some part of the auricle, that it is transmitted through the auricle and bundle of His to the ventricles, and that the auricles have almost completely lost their power of contractility. This state of affairs, though found in long-standing cases of auricular fibrillation, from a practical point of view is less inconvenient to the patient than when the auricles are actively fibrillating, and when the ventricle in spite of treatment continues to beat at a very rapid rate, or when the rate is greatly increased by the least excitement or exertion.

Summary and Conclusions.

1. The three most constant and diagnosable signs found in auricular fibrillation are: (1) the irregular irregularity in rhythm, (2) enlarged transverse diameter of the heart, (3) a difference in the apex- and pulse-rate.

2. An irregular irregular heart rhythm is almost pathognomonic of auricular fibrillation. It must be differentiated from that found in (*a*) multiple premature beats, especially those of auricular origin, and (*b*) sino-auricular heart-block.

3. There are no symptoms pathognomonic of auricular fibrillation, nor are there any much more suggestive of this than of other cardiac conditions.

4. A diagnosis of auricular fibrillation having been made it is essential to consider (1) the pathological condition of the heart which led to this condition, and (2) the effect that the fibrillation will have on the circulation as a whole, and especially on the left ventricle.

5. It is desirable to decide whether there is myocardial change in the auricles alone, or whether the ventricles also are affected. If the latter is the case, the prognosis is distinctly worse.

6. The main object to be achieved when treating auricular fibrillation is to adjust the rate of the ventricles so as to produce an adequate circulation without undue ventricular work.

7. The great therapeutic agent is rest—physical, mental, and cardiac.

---

[4] In these cases the murmur was due to the forcing of the blood by a more or less hypertrophied left auricle through the narrowed mitral opening. In auricular fibrillation this action is absent and hence the associated mitral stenosis both as a pathological condition and as the possible underlying cause of auricular fibrillation is often missed. Clinically, however, some patients with auricular fibrillation still give what appears as a presystolic murmur on auscultation. Leaving out of consideration Flint's murmur, a presystolic murmur rarely heard at the apex in aortic regurgitation, these can be divided into two types: 1. Those in which the presystolic is not a true recognised presystolic, but in which the diastolic murmur runs through the period of diastole into the following systole, the heart rest period being short. It is really, then, a diminuendo murmur instead of a crescendo murmur. When the rest period is long, on the other hand, the diastolic murmur ends as usual and there is a distinct interval previous to the following systole. 2. Among my cases there were two in which there was a distinct and true definite presystolic murmur not a prolonged diastolic, and in which there was also fibrillation. There was also a presystolic thrill palpable. The murmur and thrill were present only occasionally and of varying force. It was quite clear, however, that these did not have any relationship to the period between diastole and the following systole. It may be inferred that there is a definite stage between the normal auricular contraction and a condition of auricular fibrillation. Though the impulses are generated there is not a definite complete contraction preceding and in normal relation to the ventricular contraction, but there are a sufficient number of groups of fibres contracting simultaneously to produce a distinct murmur on forcing the blood through the stenosed mitral valve at or near the time when the ordinary presystolic murmur of mitral stenosis would be heard the heart not fibrillating. If the presystolic murmur had ared one might have inferred that it was due to occasional ls of normal cardiac rhythm.

[5] It is interesting to note in this connexion that, according to some authorities, 40 per cent. of the ventricular filling in the normal heart is performed by the auricles.

8. The commonest antecedent disease is rheumatic fever. Rheumatic fever or chorea was found in 39 per cent. of the total number questioned, while 19 per cent. of the total gave a history of no previous illness. Graves's disease very definitely leads to fibrillation.

9. Primary myocardial involvement was found in as many cases as were associated with pure mitral stenosis. The other conditions in the order of their frequency were mitral regurgitation, both mitral and aortic disease, and lastly, aortic disease alone.

10. Fibrillation of the auricles can continue until the auricles are completely exhausted and become practically a passive chamber. The contractions may then come on only occasionally and be very slight, but impulses will still be transmitted to the ventricles.

11. There is no predisposition in either sex towards fibrillation.

12. As the pulse-rate usually does not give the ventricular rate of contraction, it is necessary in all cases of auricular fibrillation to count the apex-rate as well.

13. A murmur presystolic in time can be heard in some cases of auricular fibrillation associated with mitral stenosis, but this is usually due to a diastolic murmur running into the following systole when the rest period is short.

14. 25 per cent. of all patients admitted into the wards of the National Hospital for Diseases of the Heart have auricular fibrillation.

I have to thank Dr. J. Strickland Goodall for his invaluable help and kind interest in the preparation of this paper, and also Drs. R. O. Moon, S. Russell Wells, P. Hamill, and F. Price for permission to use the cases admitted under them.

PERCENTAGE AND FRACTIONAL DILUTIONS.

BY B. BLACKLOCK, M.D. EDIN.

(From the Liverpool School of Tropical Medicine.)

IN THE LANCET of Jan. 29th, p. 223, Dr. William Fletcher gives formulæ for preparing percentages of fluids and for fractional dilutions. Professor J. W. W. Stephens and Dr. S. R. Christophers gave 12 years ago[1] a simple formula for obtaining percentage dilutions. It shows the amount of diluting fluid which it is necessary to add to 1 volume of fluid of percentage x in order to reduce that volume to the desired percentage y. The formula is $\frac{x}{y} - 1$; where x represents the original percentage and y the desired percentage. Thus, to dilute a solution from 20 per cent. to 5 per cent. add to each volume of solution $\frac{20}{5} - 1 = 3$ of the diluting fluid.

The following formula can be used where it is necessary to prepare specified volumes of lower percentage or higher dilution from higher percentages and lower dilutions respectively.

Percentage dilution.—To prepare a specified volume z of a y per cent. solution from an x per cent. solution, take of the latter $\frac{z \times y}{x}$ volume and make up to z volume with diluting fluid.

Example.—To obtain 12 c.cm. of a 24 per cent. solution from an 80 per cent. solution, take of the latter $\frac{12 \times 24}{80} = 3{\cdot}6$ c.cm., and make up to 12 c.cm. with diluting fluid.

Fractional dilution.—To prepare a specified volume z of a $\frac{1}{y}$ dilution from a $\frac{1}{x}$ dilution, take of the latter $\frac{z \times x}{y}$ volume and make up to z volume with diluting fluid.

Example.—To obtain 60 minims of a $\frac{1}{100}$ dilution from a $\frac{1}{10}$ dilution, take of the latter $\frac{60 \times 10}{100} = 6$ minims, and make up to 60 minims with diluting fluid.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A NOTE ON

NON-INFECTIVE THROMBOSIS OF PELVIC AND ABDOMINAL VEINS.

BY R. J. MORRIS, C.B.E., M.D. DURH., M.R.C.P. LOND.

INTRAVASCULAR clotting (thrombosis) may occur under imperfectly understood conditions; this is particularly true of non-infective thrombosis. The following case is illustrative; the cause is obscure, the termination unusual, and the difficulty of diagnosis from the initial symptoms is apparent.

M. D., aged 59, weight 15 st. 2 lb., height 5 ft. 11 in. Always had good health; no venereal disease; led an active athletic life; wore a double inguinal truss since April, 1918. No serious illness up to August, 1918, when he had an operation for appendicitis. Recovery appeared to be complete and satisfactory. He resumed military duty six weeks after the operation, and remained in excellent health up to April, 1919, when he had a severe attack of influenza affecting throat and chest. After four weeks he made a satisfactory recovery, and was in usual health up to Nov. 5th, 1919.

On the 5th he had much abdominal distension, slight abdominal pain, pain in area of prostate gland, congestion of penis and a very thin urine stream, took considerable time to empty the bladder; the congestion was less and the bladder was emptied with more ease in the recumbent position than when standing up. On the 6th, during a round of golf, he felt an acute pain over the left sacro-iliac joint. The next day the pain was more acute in the back, and he had a feeling of great abdominal distension, and some nausea and vomiting. On examination a fibrositic nodule over the left sacro-iliac joint, some tenderness over the gall-bladder, and slight œdema of right foot were found. Temperature normal, heart and lungs normal, pulse 68. No cause could be found for the distension and œdema, and there was no notable point in the history of the case except that he had been taking an aperient dose of Epsom salts in a glass of hot water before breakfast since the attack of influenza in April, 1919. No definite diagnosis could be made.

On the 8th he was seen by surgeon in consultation. Much abdominal distension. Dull continuous pain in abdomen; pain in back more acute; tenderness on pressure over the external abdominal rings. Examination per rectum revealed nothing. Condition remained the same up to the 11th, when in addition to the abdominal pain and distension acute pain commenced in right thigh, and pain over the femoral vessels in Scarpa's triangle. No tenderness on pressure. Œdema of both feet. On the 12th again seen in consultation. Abdominal pain and distension more marked. Temperature 99° F. Urine had trace of albumin, and on centrifugalisation a few red blood cells were seen. An elastic swelling found in right lumbar region. On the 14th left thigh became painful. Much tenderness in Scarpa's triangle. Temperature rose to 101·2°. On the 16th right thigh and groin more painful, and much œdema of both legs from hips to toes. No œdema of back. Temperature varied from 101·2° to 99·6° during the day.

On the 17th examination per rectum revealed nothing further than some ballooning and emptiness. Urine loaded with urates. Fluid appeared in tunica vag. testis. Acute pain to right of umbilicus. Temperature 99°. Œdema of legs increased, much pain in legs, no tenderness. On the 20th he was seen by surgeon in consultation. He found "a definite 'pappy' or semi-elastic swelling in right lumbar region, felt bi-manually in neighbourhood of right kidney." Discussion ensued on the possibility of the condition being inflammatory (diverticulitis). Temperature varied between normal and 99·8°. Castor oil emulsion by the mouth, and simple enemas were given daily; good result, and the tumour in lumbar region rapidly diminished in size.

By the 22nd condition improved; abdominal pain ceased; pains in both legs became less; œdema remained about the same and confined to legs; no œdema or swelling of back, and not higher than Poupart's ligament. Abdominal distension still continued. On the 23rd pains in legs and much abdominal distension, with pain and tenderness in right half of abdomen. Temperature 99·8°. On the 24th griping pain in abdomen caused restlessness, but less aching in legs, and less pain and tenderness in Scarpa's triangles. Temperature normal or subnormal. Blood examination: hæmoglobin, 92 per cent.; red cells, 5,200,000; white cells, 9100. Urine: minute trace of albumin, centrifugalised deposit showed red blood cells in small numbers.

On the 29th consultation with the two surgeons. Operation was discussed and the decision come to not to operate. Discussion followed on the probability of the tumour being malignant and partially occluding the inferior vena cava. From this date up to Dec. 4th condition remained about the same, œdema tending to subside. Pain and tenderness remained along the femoral vessels in both legs, in Scarpa's triangles, and Hunter's canal. Weight was found to be increased by 2 lb., accounted for by the fluid in the tissues of the legs. On the 12th patient was partially dressed and walked a little in bedroom; much aching in both legs followed and œdema increased. Notwithstanding this, he got up each day for varying periods and steadily improved from this date.

On Jan. 7th, sixty-fourth day of the illness, consultation of physicians and surgeons. Tumour in right lumbar region much smaller and difficult to locate. Change of air and scene recommended. Arrived Hyères, France, Jan. 31st, 1920, and returned May 7th.

Present condition, December, 1920, more than 12 months since illness commenced: In good health. Tumour right lumbar region disappeared about Jan. 16th. Urine normal, slight congestion of penis remains. Weight 15 st. 9 lb., as compared with usual weight 15 st. 2 lb. Can walk well and play golf. Very slight œdema over the tibiæ occasionally and some blueness about the ankles at night, never present in the morning. Slight dilatation of superficial veins of anterior surface of abdomen. No varicose veins anywhere. *He has discarded his truss and feels no inconvenience* in consequence.

Remarks.

The cause of the condition in this case is obscure. The purging by daily doses of magnesium sulphate may have caused the original phlebitis in the hæmorrhoidal or veins of the vesico-prostatic plexus. The attack of influenza in April, 1919, or the appendicitis and operation in August, 1918, may have left some smouldering trouble, or pressure by the double inguinal truss worn regularly from April, 1918, up to the time of the operation, and after the operation up to Nov. 5th, 1919. The first signs were abdominal distension, congestion of penis, difficulty in passing urine, and pain in right groin about the position of Scarpa's triangle; then followed tenderness over the colon, much distension and partial paralysis of it, evidently due to interference with the venous supply, œdema of right foot, pain in right thigh followed by pain, swelling, and œdema of the whole leg, but no apparent inflammation of the femoral veins. On Nov. 14th the left thigh became painful, swollen, and œdematous, with pain along the course of the vessels. It is reasonable to conclude that the initial lesion was thrombosis of one of the veins of the vesico-prostatic plexus spreading to the internal iliac and thence probably to the inferior vena cava. It is difficult in this case to decide how far in this direction the thrombosis advanced, as there was no swelling or œdema of the back, or higher than Poupart's ligament in front. As the course of the case ended in recovery it is difficult to explain how resolution came about, and why the thrombus was non-infective. The highest temperature was 101·2°; it became normal about the nineteenth day of the illness and remained so. The diagnostic alternatives were malignant tumour, inflammatory tumour (diverticulitis), fibrous tumour or contracting cicatrix obstructing the inferior vena cava.

A SECOND ATTACK OF CHICKEN-POX.

By FREDERIC HOLLAND THOMSON, M.B., C.M. ABERD.,

MEDICAL SUPERINTENDENT, NORTH-EASTERN HOSPITAL, TOTTENHAM.

MOST authorities in this country consider that a second attack of chicken-pox in the same individual is rare. For example, J. MacCombie, in his long experience, had never seen a case, and some observers seem inclined to be sceptical of its occurrence. Therefore, the following case may be of interest and seems worth recording:—

A. K., aged 5½ years, was admitted to this hospital in November, 1917, suffering from scarlet fever and with a *history of having* suffered from chicken-pox. On his chest and forehead were old scars identical with those left by chicken-pox.

In the ward in which he was resident the following cases of chicken-pox arose: L. B., aged 6 years, showed the eruption on Dec. 24th; R. F., aged 6, and D. V., aged 4, on Dec. 25th. A. K. developed a typical eruption of chicken-pox on Jan. 10th, 1918.

A NOTE ON

THE "STERNO-HYOID" ARTERY.

By LAMBERT ROGERS, M.R.C.S. ENG., L.R.C.P. LOND.,

DEMONSTRATOR IN ANATOMY AND HOUSE SURGEON, MIDDLESEX HOSPITAL.

Kocher believed one of the most important factors in operations for exophthalmic goitre to be avoidance of hæmorrhage. Referring to excision, he states: "*The* result really depends for success on the most careful arrest of hæmorrhage," a view thoroughly endorsed by Mr. James Berry and others. Apart from Graves's disease and old toxic goitres (so-called secondary [illegible]'s disease), operations for simple goitres are often associated with much blood loss, and since thyroidectomies of varying extent are becoming more frequent, it may not be inappropriate to draw attention to a source of hæmorrhage in an unnamed, but relatively large, vessel shown by recent dissections to be a muscular branch of the superior thyroid artery. Moreover, reference to the literature has revealed only the briefest mention of the muscular branches of the artery.

The superior thyroid, after giving off its hyoid, superior laryngeal and sterno-mastoid branches, frequently divides into two trunks of almost equal calibre. This bifurcation has been noticed in the carotid triangle or immediately behind the anterior belly of the omohyoid but may occur farther forward in the muscular triangle. Of the divisions, the larger runs downwards and inwards behind the sterno-thyroid to end in the gland, the other superficial to this muscle lying in a groove between the insertion of the latter and the thyro-hyoid. In this position it gives off branches to the infra-hyoids and continues downwards in a more nearly vertical course, giving rise to the crico-thyroid artery, and may here give off twigs either to the lateral lobe or the pyramid where one exists. Of the muscular branches proceeding from this division by far the largest is that to the sterno-hyoid (see diagram). This branch enters the muscle high up, roughly at the junction of the upper and middle thirds, and on its posterior aspect.

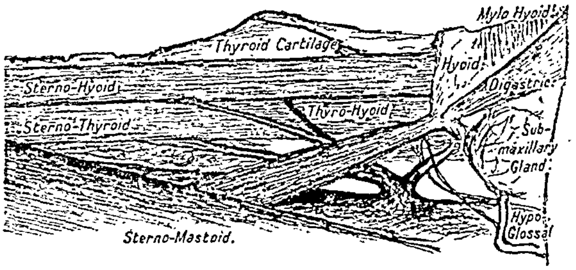

Diagram of artery.—In this case there is a common origin for the superior thyroid and the lingual. The branch to the sterno-hyoid is marked in black.

Professor Thomas Yeates is aware of the existence of the artery, and has noticed it repeatedly, and Mr. Berry tells me that when he has to divide the sterno-hyoid muscle this vessel usually requires a ligature. Professor Kocher refers to the large anterior branch as a guide to the main trunk of the superior thyroid in ligating the latter, and it is from this branch that the sterno-hyoid twig arises. It is hoped that the description may be of use to workers in this region, since it would appear that this vessel is liable to damage in thyroid operations, particularly when division of the infra-hyoids is found necessary.

A CASE OF

CHRONIC HYDROCEPHALUS SIMULATING HYSTERIA.

By M. S. MONIER-WILLIAMS, M.A. OXON., M.R.C.S., L.R.C.P., LOND.

With Post-mortem Notes by HELEN INGLEBY, M.B., B.S. LOND., M.R.C.P. LOND.

THE following case appears of sufficient interest to be recorded:—

The patient, a man of well-marked neurotic temperament, enjoyed average good health until he joined the R.N.V.R. in 1914 at the age of 46. Exposure on anti-aircraft service caused frequent attacks of bronchitis, so that he was invalided out of the Navy. In the spring of 1917, he had a severe attack of influenza *followed by meningitis according to the diagnosis* of Dr. Philip Birch, who was then attending him, and of Dr. F. W. Tunnicliffe. He first came under my care in the spring of 1918 with the following symptoms: Chronic headache (dating back to the meningitis) and "a curious pain from between the shoulders up the spine to the back of the head." The pain was associated with nausea, and there were occasional attacks of retching, but no actual vomiting. He walked with difficulty, like a very old man, "because his legs felt weak, and because it hurt his head to walk." He was inclined to be drowsy, and complained that he slept too much. He had a cough which caused intolerable pain in the head which, on examination, was shown to be due to bronchitis, and, as he breathed with difficulty, and air entry, particularly on the right side of the chest, was deficient, I sent him to Dr. A. C. Jordan for X ray examination. Dr. Jordan reported peribronchial fibrosis in both lungs, probably phthisical, the impairment being most pronounced on the right side. Sputum examined on several occasions by Dr. John Matthews showed no tubercle bacilli. The blood, also examined by Dr. Matthews, gave a negative Wassermann reaction. There was no optic neuritis.

A year later the patient's condition was much the same, except that he now suffered from occasional attacks of giddiness, was subject to slight febrile attacks now and again, had worse headache, and more frequent attacks of nausea and retching, walked with more difficulty, found it an effort to get in and out of chairs, talked at times vaguely and rather childishly, and had a strange manner, and an obviously failing memory. He visited St. Margaret's Bay, Dover, and was there taken suddenly with his final illness which lasted about six weeks. Constant giddiness and nausea, with much increased loss of power in the legs, was followed by vomiting, which was almost continuous for a fortnight, and there was steadily progressive vacant loss of memory. When the vomiting had abated he was brought back to London in a motor ambulance.

The diagnosis being extremely obscure, several consultations were arranged. Dr. Arthur Latham considered that he was not tuberculous and that the lung condition was an unessential part of his illness. Mr. Seccombe Hett excluded any gross lesion of throat, nose, and accessory sinuses. Sir James Purves Stewart found no evidence of any organic affection of the cerebro-spinal nervous system. The only objective abnormality he noted was a slight flattening of both pupils, so that they were not completely circular. He drew attention to the similarity of the patient's gait to that seen in hysterical conditions, and considered that the case was probably one of hysteria. Sir Humphry Rolleston offered no positive diagnosis, but made several suggestions, and named chronic hydrocephalus as a possible cause of the condition.

The patient's state now rapidly grew worse. He behaved as one suffering from dementia, and later developed incontinence of fæces and retention of urine. Catheterisation performed with the usual aseptic precautions was followed by acute hæmorrhagic cystitis, and coma of 24 hours' duration preceded death.

A post-mortem examination, at which Sir Humphry Rolleston was present, was performed eight hours after death by Dr. Helen Ingleby, who very kindly adds her notes.

Post-mortem Examination.

A thin body. There were old-standing adhesions of the right pleura, none of the left. The lungs showed a remarkable puckering and furrowing of their posterior surfaces at the level of the hilum, the upper halves of both lower lobes being the parts chiefly involved. In either lung a hard mass could be felt in the region of the hilum, and this on section proved to be due to extensive peribronchial fibrosis. Smaller areas of fibrosis were scattered throughout the lung tissue. The apices, however, remained free from disease. No signs of active tuberculosis were found, but calcareous changes had taken place in the peribronchial glands. Compensatory emphysema was in evidence in the non-fibrosed areas. The bronchi were somewhat thickened and dilated, but there was no acute bronchitis.

The heart showed nothing abnormal beyond slight right-sided dilatation. The vessels were remarkably free from atheroma. Below the diaphragm the most interesting lesion was in the bladder, which was full of blood, and showed severe hæmorrhagic cystitis with sloughing of the mucous membrane. The condition was apparently akin to the acute bedsore that sometimes develops in cerebral cases. The kidneys and prostate were normal. In the other abdominal organs the only noteworthy feature was a fairly marked perilobular fibrosis of the pancreas.

Cranium: The brain was moderately injected. Old adhesions were present between the lobes, and especially between the medulla and cerebellum. The pia-arachnoid was somewhat thickened. The brain substance was soft, and the ventricles distended with slightly opalescent cerebro-spinal fluid. The fluid was under considerable pressure, and spurted with some force through the infundibulum as the brain was being removed. All the ventricles, including the fourth ventricle and the aqueduct of Sylvius, were enlarged, and the foramen of Monro was about three times its normal size.

Microscopically the meningeal thickening was confirmed, the pia showing moderate infiltration with lymphocytes and plasma cells. No excess of cells was present in the cerebro-spinal fluid.

In the nerve cells the protoplasm was somewhat vacuolated and the Nissl granules disappeared from the cells in the cortex and in the medulla oblongata. Altzheimer's fuchsinophil granules were present in all the cells, but this appears to have no special significance. The nuclei were practically normal, so that one must regard the changes in the protoplasm as a terminal event. The microscopical findings thus confirm the naked-eye conclusion that chronic hydrocephalus and not structural alterations of the grey matter was responsible for the symptoms.

The total illness of the patient lasted a little over two years.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

COMBINED MEETING OF CLINICAL, MEDICAL, AND SURGICAL SECTIONS.

GRAVES'S DISEASE: ITS MEDICAL AND SURGICAL TREATMENT.

A COMBINED meeting of these sections was held on Feb. 11th, Sir ANTHONY BOWLBY, President of the Clinical Section, being in the chair.

The Medical Side.

Dr. HECTOR MACKENZIE, who opened the discussion, spoke of the advantages offered by surgical treatment in saving patients from suffering for long periods of ill-health. He related two typical cases of long-standing exophthalmic goitre in which the patients had been treated medically; most of the symptoms and signs of the disease had disappeared, but in one case the heart had remained rapid and irregular, and in the other there was, as well, auricular fibrillation. It was generally admitted that most of the symptoms resulted from hyperthyroidism, and the problem presented itself as to what was to be done to reduce the over-secretion of the thyroid gland. There were two methods of bringing this about: (1) X ray radiation, and (2) by surgical treatment. He had tried X ray treatment in a considerable number of cases, but it was not until 1915 that he met with any convincing evidence of its efficacy. In this case the patient, after treatment in the X ray department, presented herself without any signs of Graves's disease, but evidently suffering from myxœdema. The goitre had entirely disappeared, the eyes were normal, and the heart was quiet. She quickly lost the symptoms of myxœdema under thyroid treatment and then appeared normal in every way. After this he had had a large number of cases so treated, but on the whole he considered the results as having been very disappointing. He had seen another case in which, although there was practically a cure, yet there resulted a severe X ray burn, followed by keloid growth. The cure, which was brought about by X ray treatment even in only a few cases, went far to establish the truth that the essential nature of exophthalmic goitre was hyperthyroidism. The conclusions he had come to from the results of his own observations were that in many cases there was no obvious benefit, and that even with many applications over a long period of time a cure was very rarely effected. The danger of X ray burning, too, must not be forgotten.

Dr. Mackenzie then considered the surgical treatment, the pioneer in which, he said, was Lord Lister, who, in 1877, removed the greater part of a goitre in a case of Graves's disease, in which the patient's life was in danger from suffocation. A few weeks later all the symptoms were alleviated, and it was recorded that after another 10 years the patient presented few signs of her former malady. This successful result encouraged other surgeons to perform similar operations, but the risks to life were found to be so considerable that for many years not many cases were treated in this way, at any rate in this country. Encouraged by the reports of Kocher and others he had now and again ventured to have recourse to operative treatment for his patients, but his experience was most disheartening at this time, for the operation under general anæsthesia proved fatal in a number of cases. Ligature of the thyroid arteries came into vogue in the first decade of this c
although comparatively safe, did not appear
be followed by such improvement as to
while to go on with it. The in
anæsthesia and advances in surgical
great reduction in the operative mortality.

At a former discussion of the R
Medicine on the subject Mr. T. P. Dunhill
a series of cases of exophthalmic goitre
under local anæsthesia, and followed by

tory results; and in 1915 Mr. Dunhill had successfully operated upon a severe case of his (Dr. Mackenzie's), using a local anæsthetic. Mr. Dunhill had initiated the late Mr. Stewart Rouquette and, after his untimely death, Mr. W. H. C. Romanis into his technique, and with the collaboration of these various surgeons he (Dr. Mackenzie) had been able to apply surgical treatment to all those cases in which he thought it was indicated. He thought that the leading principle for selection of cases suitable for operation was that a fair trial had been given to medical treatment and that the case had shown no real improvement. Any surgeon who was unduly influenced by statistics would probably have declined to operate on most of them. Of 30 private cases successfully operated upon the average duration of symptoms before operation had been nearly four years, and the cases had all been more or less severe; some had required more than one operation. The usual immediate results following partial thyroidectomy were: (1) the patient became restful and tranquil; (2) there was an increase in strength; and (3) the heart's action became slower, but this might only come about gradually. When only one lobe was removed amelioration was sometimes the most which followed, and further operation was necessary to bring about the best result. The prospects of the patient with one lobe removed were much better than they would have been without the operation. Exophthalmos appeared to be the most persistent symptom, but although the eyes remained prominent the staring frightened look was lost. Among several hundreds of cases of operation, private and hospital combined, there had not been more than 2 per cent. of deaths.

Dr. Mackenzie then discussed the contra-indications to operation. One would have thought, he said, that auricular fibrillation was one, but he had had several cases operated upon in which this had been present and the result of the operation had been that the heart had become quiet and regular. He had ventured on operation in a case in which the patient was bordering on mental derangement, and after operation the nocturnal delusions disappeared. He thought that, as a rule, mental symptoms should contra-indicate. In the presence of undoubted diabetes operation should not be performed. Fear or dread of the operation was another contra-indication. He had seen one case in which an air raid had come on after the patient had been prepared for operation; the pulse went up to 200 and the patient died from fright. At the present time there were probably some members of the profession who were altogether opposed to the surgical treatment of exophthalmic goitre. They had exaggerated ideas of the dangers of operation, and they shut their eyes to, or were ignorant of, the benefits which it brought about, and possibly they expected more from the results of surgical treatment than experience justified. On the other hand, there might be some who would advocate surgical treatment without delay in every case. Both would be wrong in his opinion. The patient should have a fair trial of medical treatment, but if he or she did not improve within a reasonable time the possible benefits of surgical treatment should be mentioned and the patient given a chance of taking advantage of them. To his knowledge there was no other treatment available at the present time which offered so good a prospect of restoration to health and vigour.

The Surgical Side.

Mr. **James Berry**, who opened the discussion from the surgical side, said that he felt deeply the responsibility which devolved upon him in opening the debate from the surgical aspect and trusted that the statements which he would make would be regarded as but the expression of opinion of an individual based in the main upon his own personal experiences. By speaking somewhat dogmatically he hoped to evoke criticism and a good discussion. In 1914, in the *British Journal of Surgery*, he had gone very fully into the whole subject, and since that time his views had undergone but [illegible]vely little change. A wider experience, however, had led him to take, on the whole, a somewhat less sanguine view of the advantages of operation than he did then, mainly on the ground of the tendency to relapse after even the most successful operation, and the incompleteness of the cure in many cases which at first sight seemed most favourable. He was glad to see at the meeting many surgeons of large experience in this branch of surgery who would doubtless tell of their own results and probably differ from him in many of his conclusions. He was especially glad to see there his friend Mr. Dunhill, who had recently forsaken the antipodes and come to place his talents at the service of this country. He would begin by making two statements which would not, he thought, be controverted by anyone who had had large experience of these operations.

1. That the usual result of an operation for exophthalmic goitre was that within a very short space of time, generally within a few days, the patient felt that she had derived *immense benefit* from the operation. The feeling of illness, of wretchedness, of depression quickly disappeared. The tachycardia often diminished very greatly, and might disappear completely in a few weeks. Exophthalmos was often lessened, although complete disappearance was much less common. The amount of benefit depended largely, but by no means wholly, upon the amount of gland that had been removed.

2. The operation for removal of an exophthalmic goitre, even when skilfully performed and carried out under the best conditions, involved *considerable danger to life*, a danger which was far greater than that for simple goitre. The mortality of these latter operations had now been reduced by most surgeons familiar with thyroid surgery to a mere fraction of 1 per cent., due to complications and accidents.

The operation for removal of true exophthalmic goitre involved a mortality of at least 3 to 5 per cent., and it was well known that many series of such operations, although mostly unpublished, gave a far higher mortality than this. Too much stress must not, however, be laid upon mere mortality. The disease was undoubtedly a very serious one and a mortality of even 5 per cent. was one that most patients suffering severely from the disease would willingly undergo if the operation offered a good chance of complete and permanent cure. He would like to state that he was speaking only of true exophthalmic goitre, and that he did not include those numerous cases of simple goitre accompanied, as they often were, by palpitation, tremor, &c. Such cases did not develop exophthalmos, and their inclusion in statistics of exophthalmic goitre was wholly misleading. They did not show the characteristic pathological changes in the thyroid gland, and the mortality of operations upon them was little, if at all, higher than it was in simple goitre.

Five Questions for the Surgeon.

He suggested for discussion: 1. What surgical treatment should be adopted for exophthalmic goitre. 2. When operation should be performed. 3. How it should be performed. 4. How the patient should be treated afterwards. 5. The question of relapse.

1. Of the numerous operations open to us he would confine himself to the only two which, in his opinion, had any real value—namely, removal of a portion of the thyroid gland, and ligation of thyroid arteries, the only two which he himself performed. Operations upon the sympathetic, exothyropexy, injections of boiling water and other substances into the gland he did not think worth discussion. The operation of removal of the thymus gland, which was always enlarged in cases of true exophthalmic goitre, was an operation much praised by some. It might be valuable, but he had no personal experience of it, and he did not think that sufficient proof of its value had yet been adduced. It was often very difficult or impossible to perform, and owing to the intimate relations of this gland to the innominate vein and pericardium the removal of any considerable portion of it must involve considerable danger. Ligation of the inferior thyroid artery he had completely abandoned, as it was a difficult operation, scarcely inferior in difficulty and danger to removal of a lobe, which was far more likely to cure the disease. Ligation of the superior thyroid had the very great advantage of being a comparatively easy, short and, on the whole, a very safe operation. He had not lost a case for more than eight years, during which time he had performed a large number of these operations. In itself it often did much to improve the

patient's condition and afforded the surgeon valuable means of judging whether he could, *if necessary, proceed* subsequently to the larger operation of thyroidectomy. It was most suitable for cases of large exophthalmic goitres in patients who were either acutely ill or suffering severely from visceral complications. But it could not be done with impunity in every case.

Mr. Berry showed the following table giving particulars of his operations of ligation of the superior thyroid artery for exophthalmic goitre during the years 1913 to 1919 inclusive:—

Hospital Cases Only.

Patients—Male 1, females 27; total 28.

Operations ...	Bilateral simultaneous ...	5 patients	= 10 arteries.
	Bilateral at different times	14 „	= 28 „
	Unilateral	9 „	= 9 „
		28 „	= 47 „
		= 42 operations.	

There were no deaths in any of these cases or in any of the private cases during this period. Nine of the patients subsequently underwent extirpation of one lobe. The main question of interest with regard to removal of the gland was how much should be removed. He had almost abandoned the practice of operating simultaneously upon both lobes, as in most cases he thought it involved too much risk to life. *Nor did he now usually remove* even the whole of one lobe. He always left a small portion at the hilus, and he liked to leave a good deal of the posterior capsule. Among other reasons, damage to the recurrent laryngeal nerve was much more likely to occur if the whole of the posterior capsule were removed. Enucleation or "shelling out" operations should, of course, never be attempted in any case of true exophthalmic goitre, except in those very rare cases in which true Graves's disease was superadded to an old encapsuled cystic or solid adenoma. These cases were quite distinct from those of the so-called "toxic adenoma," in which there was little danger more than that of any ordinary goitre operation.

2. When operation should be performed. There were, he thought, some surgeons who operated upon nearly every case, independent of the stage which the disease had reached and of the complications, especially cardiac, which might exist. Although personally he believed this to be a mistake, it would be interesting to learn what results, immediate and remote, followed such a practice. He believed that it was wrong to do thyroidectomy when the patient was suffering from very acute mental excitement, or when the visceral complications, *especially myocardial degeneration*, were very marked. But sometimes a mere ligation was permissible under conditions which would preclude the performance of the larger operation. In Graves's disease there were generally periods of remission during which operation might be undertaken with much greater safety than at the other times. It was just during the period of exacerbation when the patient, and often the general practitioner, and sometimes the physician, were most anxious for operation, and when *the surgeon should resist* the temptation to operate at a time when his better judgment should tell him that this ought not to be done. He would also add that operation should never be performed until the patient had been resting quietly in hospital or nursing home for at least a few days and had become accustomed to the new surroundings. On the other hand, he did not operate at any stage upon patients who were steadily and continuously improving, and especially upon patients, and there were many such, *who did not feel at all ill. Operations* under such conditions were, he thought, unnecessary. He never tried to persuade a patient to be operated upon against her own wish. The converse was very much more likely to occur, since he found that most really bad cases of exophthalmic goitre were only too willing to submit to any operation that afforded a prospect of cure. He never tried to "steal the gland" by not telling the patient when the operation was to be done. On the contrary, he thought that it was much better to gain the *patient's confidence* by talking to her frankly of the discomfort that she must expect to undergo, and that she would probably feel very ill for a day or two. By doing so a patient was much less likely to be frightened and excitable *after* the operation at a time when it was *important* that she should keep quiet.

3. How the operation should be done. The ordinary rules for removal of a goitre should be followed, the greatest possible care being taken with hæmostasis and, of course, with asepsis. No kind of antiseptic should ever be put into the wound. The question of anæsthesia was a very important one. He was coming more and more to believe that a very light open ether anæsthesia was preferable for most cases, although undoubtedly there were some in which local *anæsthesia* was preferable if the patient had sufficient resolution to stand what was undoubtedly a very disagreeable performance. There were some surgeons, he knew, and he thought more physicians, who thought that the use of a local anæsthetic was the main factor of safety *in the operation. But it was by no* means the only factor, and was not even, in his opinion, the main one. The method of operating varied a good deal according to the shape and size of the goitre and especially as regarded the size of the isthmus. The rigidity and solidity of the goitre and the presence of a thick isthmus often made the operation extremely difficult, especially at the stage of ligation, in its continuity, of the inferior thyroid artery. This was an important step in the operation, which was nevertheless sometimes impossible to execute. It was here that the aid of a really skilled assistant was most valuable, as he could sometimes, with one finger, control temporarily the circulation through this artery when it *could not be reached* for ligation. He would here express the opinion that except in some cases of acute intoxication and of myocardial degeneration it was usually hæmorrhage—sheer hæmorrhage—that was the main cause of death after removal of an exophthalmic goitre as ordinarily performed. Even a comparatively small amount of hæmorrhage which would be of little or no importance in a case of ordinary goitre might easily prove fatal in an exophthalmic one. He left the important question of the heart to be dealt with by Dr. Strickland Goodall.

4. The after-treatment might be summed up in the single word "water." The patient must be encouraged to drink large quantities (many pints) of water, or if a general anæsthetic had been employed, large quantities of saline solution must be introduced into the rectum by the continuous-drop method, care being taken that the rectum was never distended. In one rather exceptional case of his, which recovered, as much as 18 pints of fluid were absorbed in the first 24 hours, but the absorption of 8–10 pints of fluid in this period was not unusual. It was here that the services of a skilled nurse, trained in the after-treatment of these cases, was most valuable. Drugs were of little value in the after-treatment, as far as he was aware.

5. Relapse. There was no doubt that a good many patients who had made good recoveries from the operations and had remained well, or practically well *for considerable periods of time, were liable to relapse, and they might even* die of the disease. In some of these cases a second operation was advisable, more gland being removed. But there was a limit to the amount of gland that could be removed, lest the ultimate condition of the patient, although different, might be as bad as, or even worse than, the first. Some of the operations, the results of which were recorded in the table (shown) were second operations, a primary operation having previously been performed either by himself or by *other surgeons.*

A table of the ultimate results of 79 operations (upon 78 patients) for removal of true exophthalmic goitre (excluding mere ligations) during the seven years, *1913–1919*, was shown; *53* of the patients were practically well, 18 were much improved, 3 were but little or not at all improved, 1 was worse, and 3 died as the result of the operation. Several patients who had undergone operation were exhibited, together with photographs and pathological specimens.

Outlook Apart from Operation.

Mr. T. P. DUNHILL spoke on three aspects of the question: (1) the grounds on which he considered some intervention other than medical to be necessary in some cases; (2) what degree of improvement *could* be obtained by surgical methods; (3) what permanence one might expect in this improvement. With regard to the first point as to whether there was any necessity to consider surgical treatment, he said *that death was not* the only tragedy in Graves's disease. The late Mr. Jessop had collected 25 cases of Graves's disease in which an eye was lost, due to ulceration occurring through the extreme proptosis. *He himself had had two* cases in which an eye was lost and another in which haziness of the cornea resulted. He had seen auricular fibrillation in many cases and had known it *develop* in at least three cases while they were under *medical* supervision, and he had known many cases of *generalised* œdema. Not all cases should be operated upon, *for* we all recognised that some cases recovered. *When* we had discovered which recovered, and *why they* recovered, we should have learnt much. *We did not* know the factors which enabled some *individuals* to recover an equilibrium—a glandular and *nervous* balance. No single drug would bring it *about. The* idea of operation was not to be *entertained* (1) removal of every toxic focus, (2) rest, and (3) *efficient* ptomatic drug treatment had been given *while* No *time limit* should be put to *this;*

was definite improvement which could be shown on a chart this treatment should be persevered with, but when improvement ceased, or if no improvement occurred, other measures must be considered without delay. The other measures were X ray treatment and operation. His personal experience of X ray treatment was unsatisfactory. The patients felt better while they were under treatment, but the pulse-rate had not come down, the size of the gland had not been reduced, the exophthalmos had not been altered, nor had the tremors disappeared. There was one theoretical objection against X rays. Dr. Murray stated that pathological examination of glandular tissue after X ray treatment had shown well-marked fibrosis in the gland, as well as fibrosis surrounding the alveoli and around the gland. This fibrosis continued long after the application of X rays, and might be more likely to induce myxœdema through cell-atrophy than clean removal of excess of gland tissue. He had seen many advanced cases whom he had been compelled to operate upon subsequently to X ray treatment.

What was the outlook if patients were not improving? It was said that the course of the disease ended in (1) recovery, (2) myxœdema, (3) death; but there were numbers of patients in various grades of ill-health down to the most complete bedridden wrecks. Some could do light work, some could keep going if they rested much and limited their activities. Some were very ill, but unable to rest, for a spirit of restlessness possessed them, and some were waterlogged from cardiac and renal incompetence. In some an eye was irretrievably damaged. These conditions were far more common than myxœdema, and they were not passing phases. In each of these grades there were those in whom improvement, if it occurred, took years, and those who would never improve. Long periods of most of these patients' lives had been spent in striving to get on to a higher plane of health while gradually slipping down on to a lower. He would venture to state that there were none of these cases which might not be very much improved by operation. Cases were then described and photographs were shown illustrating the improvement after operation. The patients were extremely ill and getting worse. The downward course was stopped at once when a lobe was removed, and the improvement was completed by removing the optimum amount of gland tissue. Exophthalmos would generally disappear if cases were sent for operation within a reasonable time and if sufficient gland tissue was removed. If they were kept until spasm in Müller's muscle had become a contracture, proptosis would be kept up for two reasons, first, because the muscle itself pushed the eye forwards, and secondly, because the œdema induced in the orbital cellular tissues by the contractured muscle caused further proptosis. It was not the fault of the surgeon, but of the delay in the case coming for operation which was the cause of the permanence of the exophthalmos. This symptom took longer than the others to disappear. If there had been great proptosis which disappeared, there remained a bagginess of the lids, particularly the lower one, which was very obvious. He showed photographs of patients in whom there was marked proptosis. In two an eye was lost, and in the other, while the eyes ultimately were saved, haziness of the cornea occurred. In one case in which the eye was lost the exophthalmos in the other disappeared entirely after the operation. He had operated upon many whose hearts were irregular, and upon some who suffered from proved auricular fibrillation. Not all of these had lost the fibrillation; it was a question of the length of time or the extent of the damage. He showed the electro-cardiographic tracings of the heart of a patient before and subsequent to the operation, when it showed no trace of fibrillation. The patient was now doing heavy housework.

Grade of Improvement Obtainable by Operation.

With regard to the degree of improvement which might be attained in the ordinary but severe case which was resistant to medical treatment, our criteria were the pulse-rate, the exophthalmos, the tremor, the menstrual condition, the muscular weakness, and the mental agitation. He would presently be able to use an instrument—the respiratory valve spirometer—for measuring the basal metabolic rate which would give a more accurate measurement of the degree of the disease and its amount of improvement. So far sufficient evidence had not been accumulated to record. Without using the word "cure" one might state that all these cases could be placed on an industrial level, a level where they were able to carry on their household duties, earn their living, bear children, dance, and swim. This result was not always or often going to be obtained by removing one lobe and the isthmus, or by combining this [illegible] ture of the superior artery of the opposite side. Kocher had stated that partial excision of the second lobe was only exceptionally necessary, and that it was an unsafe procedure on account of danger from hæmorrhage. He could not regard either statement as true. Many cases would not be cured without removal of a portion of the second lobe—none of the bad cases were sufficiently improved unless this was done. As regarded its safety, he had never yet lost a patient at a second operation on a case of exophthalmic goitre. This aspect of the subject demanded close scrutiny, for it was the crux of the whole matter. Physicians were dissatisfied with the degree of improvement which operation gave. Many surgeons stated that they removed one lobe, the isthmus, and perhaps ligatured an artery on the opposite side, leaving a lobe may be twice or several times as large as the normal thyroid gland, and a cure was expected. This could not be so. He knew that there were some cases in which removal of one lobe might turn the scale and allow a patient to regain an equilibrium, particularly in early cases or in cases which were very nearly winning their own battle. But this was not the kind of case which was usually sent to the surgeon. It was "unsurgical," if one might use the term, to remove sufficient at one operation. There were some cases in which one's judgment or one's instinct indicated that it should be done, but there were some in which removal of a lesser amount would improve the patient sufficiently. We had no right to remove from an individual more than was necessary to achieve the purpose, but we must remove enough. It was very important, in his opinion, to leave the blood-supply of the portion of gland which was left intact; the gland tissue would never atrophy and it would be more permanently efficient than gland in which fibrosis and cell-atrophy had been induced by X rays.

The next thing to be considered was what made for safety of operation. He knew that the death-rate was extremely low in cases operated upon at any reasonable period during the course of the disease. It rose as one was prepared to undertake grave surgical risks in order to try and save lives in cases which came far too late to the surgeon. A thyroid operation in Graves's disease differed in many respects from, say, a stomach operation, in which the chief consideration for the patient was that the work should be carefully and accurately done, and where it was not of great importance to the patient whether it took 20 minutes or 1½ hours so long as there was careful handling. An operation had never been done by him without fear and great anxiety, even in cases which seemed simple. The fear and anxiety began as soon as one knew that the operation was inevitable, and it did not cease until after the operation had been done. He would plead for earlier operation. It would be safer, it would free the patient, physician, and surgeon from anxiety, the operations would be less extensive, the tragedies, whether of death or ill-health, would be prevented, and patients would be restored to a degree of health unattainable when operation has been postponed too long.

Natural History of the Disease without Operation.

Sir WILLIAM HALE-WHITE said that before we could decide upon the proper treatment of any disease it was necessary to know the life-history of those afflicted with it. In the *Quarterly Journal of Medicine* (vol. iv., No. 13) he published the results of an inquiry into the after-history of every patient suffering from exophthalmic goitre who had been in Guy's Hospital from 1888 to 1907 and of every private patient he himself had seen. After deducting cases operated on and those which could not be traced, 102 remained for consideration. Contrasting their after-history with the expectancy of life of healthy females of the same period of life it appeared that the mortality of sufferers from exophthalmic goitre was about twice as great as it should be. This, however, gave too serious a view of the mortality, for in the first place sufferers from exophthalmic goitre were of such an age that but few healthy persons of the same age died and therefore a double mortality was not a great mortality; in the second place, his cases were all either ill enough to come into hospital or seek a second opinion. The conclusion seemed justified that persons with exophthalmic goitre had not an expected mortality much higher than normal. This was borne out by the fact that the disease was unusual in the post-mortem room. But it was rarely seen in elderly persons, therefore it must be a disease the natural tendency of which was to get well. His figures bore this out, for among the hospital-traced cases 65 per cent. got quite well, 30 per cent. were much better, and 5 per cent. were better in some respects. Among the private-traced cases 74·5 per cent. got quite well, 19·1 per cent. were much better, and 6·4 per cent.

were better. The most interesting causes of death were enteritis and diabetes. It was impossible to allude in detail to all the cases, but to show how well some of them did the following were mentioned:—

Female, aged 21: a severe case in all respects; had glycosuria. Fourteen years later was normal; no glycosuria. Female, aged 23; a very severe case. Seven and a half years later was quite well. Female, aged 29; very severe case; got practically well. Female, aged 20; severe case. Wrote 20 years later to say that she works hard and has done so for 18 years, was married, had three children, and is now a widow. Female, aged 23; medium case. Wrote to say that she was married, had six children, and had not required any treatment for 11 years.

Nowadays the difficult question that always presented itself was whether or not we should advise an operation. With the present state of our knowledge we had not sufficient evidence to answer this question. In order to do so we required the after-history, for a period of 20 years, of at least 100 cases submitted to operation. Then we could learn whether their expectancy of life was better than those not operated upon, and whether they got well sooner, for not all the cases operated upon got quite well; some were only considerably improved. We should also learn whether, having had half their gland removed, they were more liable to myxœdema, and how often they relapsed. There was also the difficulty that the slight cases hardly needed operation, and the danger of it was considerable in the very bad cases. Most of those who were especially interested in the subject could recall deaths either during or immediately after operation, and we must give the patient the opportunity of deciding whether she was willing to run this risk for the cure of a disease the natural tendency of which was to get well. Probably, however, with increasing surgical skill the risk was diminishing. The following case illustrated that an operation might be advised unnecessarily.

A woman was admitted to a surgical ward for operation for exophthalmic goitre. After she had been in a few days, and before the operation, signs of typical typhoid fever showed themselves. She was transferred to a medical ward, and under the rest in bed necessitated by the fever she got completely well of her exophthalmic goitre.

He (the speaker) was not arguing against operation, but was only urging that to bring forward a few cases shown some months after operation was not proof that surgical treatment was best, for it was as easy to show cases which had done just as well without operation. It was notorious that patients with acute peritonitis, empyema, and many other conditions did very badly if operation were not undertaken, but we knew that exophthalmic goitre was a disease the natural tendency of which was to get well, and therefore at least a hundred patients who had been operated on would have to be followed for about 20 years before we should have sufficient data from which to draw a conclusion.

Cardiac Complications.

Dr. J. STRICKLAND GOODALL said that whether patients were treated from a medical or surgical standpoint the condition of the heart was of greatest importance. Working in collaboration with Mr. Berry, he had been carrying out investigations of the heart disorder in Graves's disease, and had made many hundreds of observations. The basal metabolic rates as tested by Benedict's machine would probably prove very useful. He had recently used a modified form of the machine by which graphic records could be obtained. He had come to the conclusion that a patient suffering from Graves's disease probably died from ventricular fibrillation, in the production of which two factors were concerned—pre-existing myocardial degeneration and high blood pressure. The dangerous case was that in which there was definite myocardial degeneration, and in which the blood pressure was high. There had been differences of opinion as to the usual blood pressure in exophthalmic goitre. He thought that it was tri-phasic, the first phase being a transient rise, the second a fall, and the third a rise again.

The discussion will be resumed on Friday, Feb. 25th, at 8.30 P.M.

SECTION OF SURGERY: SUBSECTION OF ORTHOPÆDICS.

EXHIBITION OF CLINICAL CASES.

A MEETING of this section of the Royal Society of Medicine was held on Feb. 1st, Mr. E. LAMING EVANS, the President, being in the chair. Among the cases exhibited were the following.

Mr. B. WHITCHURCH HOWELL showed a case of

Dislocation of the Hip and Other Deformities.

The patient was a girl, aged 7½ years, who had never walked properly. At the age of 2 years she had had pneumonia, followed by diphtheria, after which she began to walk, and the mother stated that it was only then that she noticed that the child waddled and that the feet were deformed. There were no deformities in the family. The patient was fairly intelligent. The right lower limb was one inch shorter than the left. There was talipes equino-valgus, the knee was contracted, the hip was dislocated, and there was coxa valga. The left lower limb showed talipes calcaneo-valgus, slight wasting of the leg, paresis of the tibialis anticus, and contraction of the knee. In the spine there was a dorsi-lumbar scoliosis to the right. Walking was very difficult, the gait was stiff, but not spastic; sensation was unaffected; the left leg was distinctly colder than the right. *In the hands the little fingers were radially* deformed.

Mr. Howell asked for opinions as to diagnosis, treatment, and prognosis. He thought that the talipes was secondary to the pneumonia and diphtheria, and that the deformity of the hip was congenital.

The PRESIDENT and Mr. R. C. ELMSLIE discussed the case, and thought that all the deformities were congenital.

A Case for Diagnosis.

Mr. M. FITZMAURICE KELLY showed a case for diagnosis. It was that of a man, aged 54 years, who was injured in 1902 by a fall from a horse. There had been a fracture of the left patella, which was still ununited, and the right knee was injured. The joint was opened and drained four days later. He was in hospital for four months, and was well enough to ride again 12 months after the accident. During the war he served in the Royal Engineers, and was struck on the knee in April, 1919, while in Palestine. He remained on duty for a week, then went into hospital, and had been under treatment ever since. When seen early in January, 1921, there was great swelling of the right knee, which contained fluid, and surrounding the joint were several firm elastic masses, which did not communicate with it. The largest of these was in the region of the bursa in connexion with the insertion of the sartorius, gracilis, and semitendinosus. Movement was free and painless, but there was some aching of the joint after prolonged use. A skiagram showed the presence of opaque masses in the region of the swellings and of the supra-patellar pouch of synovial membrane; there was no bony change. The pupils were unequal and irregular but reacted normally; the knee-jerks were unobtainable owing to the condition of the knees. The Wassermann reaction was negative and there was no history of syphilis.—Mr. A. N. SHEEN thought that the condition might be tuberculous.—Mr. H. A. T. FAIRBANK suggested new growth. He thought that it was not tuberculous or syphilitic.—Mr. P. B. ROTH considered the possibility of Baker's cyst.—Mr. BLUNDELL BANKHART did not think that it was new growth. There was probably joint fluid in the most accessible swellings. He had seen gummata about a joint, but they had not felt like these swellings. He thought that it was a chronic inflammatory condition probably dating from the injury.—Mr. R. C. ELMSLIE was opposed to the theory of a chronic inflammatory condition of the synovial membrane, but thought it might be a slow-growing fibroma with cystic degeneration of the synovial membrane; it might possibly be a lipoma.

Mr. KELLY, in reply, said that he thought it unlikely to be new growth, as the swellings were multiple and separated from each other, and on account of the amount of fluid present. (Since the case was shown operation has been performed. The swelling over the inner tuberosity of the tibia consisted of a multilocular mass containing a little fluid resembling synovia, but chiefly a semi-solid mass resembling altered blood clot. A portion of this is being examined, and a further report will be communicated at a later meeting of the section.)

Mr. ASLETT BALDWIN showed a case of

Still's Disease

in a girl, aged 13, who had suffered from the disease since the age of 5 years. Both hip-joints were flexed, there were flexion and adduction of both knees, ankylosis of the left elbow, both ankles and spine. X ray examination showed considerable rarefaction of the bones of the knee-joints.

The PRESIDENT spoke of a case of Still's Disease, in which he had excised an elbow and both knees which were all ankylosed, but in this case the patient had flexible hips.—Mr. H. A. T. FAIRBANK, in discussing the treatment, said that he would employ slow methods to reduce deformity rather than active methods. The main point was to know when the disease was at an end, and this was extremely difficult owing to the fact that exacerbations usually occurred. It was very important that all active measures should be deferred until the disease was over.

Reactions and Electrical Treatment of the Intrinsic Muscles of the Foot.

Dr. MURRAY LEVICK read a paper on the rôles of some of the intrinsic muscles of the foot, and their importance in maintaining the longitudinal and transverse arches. This was followed by a demonstration of his method of treating these muscles electrically, the various groups being singled out and made to contract in response to faradic stimulation, so as to show clearly the accuracy of what he had said, and the efficacy of the treatment in certain affections of the foot. He said that the treatment was applicable to the preliminary stages of flat foot, and to the after-treatment of those more advanced cases which had been wrenched and fixed in plaster or undergone surgical operation. The rôle played by the flexors of the toes (especially flexor brevis hallucis and flexor brevis digitorum) in supporting the longitudinal arch of the foot was a very important one, because when the weight of the body was thrown forward on to the toes with the heel off the ground the action of both long and short flexors was to draw the heel towards the toes, acting as a bowstring across the arch from heel to toe. For this reason the way to land from a jump was to have the whole weight of the body borne between the balls of the feet and ends of the toes. Also when patients were given heel-raising exercises from the standing position this distribution of the weight should be carefully taught by telling them to grasp the floor with the toes, which thus became the fixed points from which their flexors acted. Flexor brevis digitorum, being inserted into the middle phalanges, was at a mechanical disadvantage in bending the toes when compared with flexor longus, and therefore acted more strongly as an arch-raiser. The flexors of the toes should be used to assist progression in walking quickly or running, those of the great toe being of special importance. If the above points were borne in mind, the efficacy of the treatment demonstrated would be clear. Graduated contraction of any of the intrinsic muscles could be obtained at will. As this treatment was carried out and the active electrode was placed in position to stimulate the desired group of muscles a clear view was gained of the action of the dorsal interossei in raising the transverse arch of the foot. It was seen that this was a strong action, and it emphasised the importance of these muscles. As the core of the coil was introduced and withdrawn, the transverse arch was seen to rise and fall in time with the rise and fall of the current, and a clear mental picture could be formed of the dorsal interossei with their bipennate origins drawing the metatarsal bones together. To describe the action of one of these muscles would suffice to explain the action of the rest, and for purposes of demonstration the second metatarsal bone was considered as the keystone and as the middle line. When [illegible]cond dorsal interosseous muscle contracted it [illegible]ed the following rôles in the order given. These [illegible]d been carefully observed during electrical stimulation of individual muscles, and then of the group as a whole.

(1) Feeble contraction. Abduction of first phalanx from middle line.

(2) Stronger contraction. Flexion of metatarsal-phalangeal joint, plus the pull on the extensor tendon. End of toe brought into contact with the ground (in voluntary movement this contact was, of course, strengthened by the flexors).

(3) Powerful contraction. The fixed points from which the muscle acted were now (*a*) the second metatarsal bone, (*b*) the insertion of the tendon into the first phalanx. As the muscle contracted the third metatarsal bone was drawn towards the second—i.e., towards the middle line. In voluntary movement the second metatarsal was fixed by the opposition of the first dorsal interosseous muscle, which also fixed the first phalanx of the second toe, and so on.

As each metatarsal bone was drawn towards the second metatarsal it was pulled into a plane below that of its more mesial neighbour. It would be seen that the arch-raising action of the dorsal interossei is very powerful and that these muscles must be regarded as of great importance. Still more strongly was the impression given of the action of the short flexors of the toes in raising the longitudinal arch, while the toes, acting as fixed points, pressed the bottom of the bath. The marked action of abductor hallucis showed how it can still be trained to assist in maintaining an improved position of the great toe when this has been corrected by mechanical means. Tibialis posticus and the long toe flexors were stimulated individually, and were seen each to raise the longitudinal arch in turn. He said that the method of treatment he had shown was strongly to be recommended as a preliminary to voluntary exercise. It was waste of time and discouraging to the patient to begin re-education before the intrinsic muscles of the foot were in at least a fair state of nutrition. He regarded it as inseparable from the satisfactory treatment of flat-foot after seeing the surprisingly good results that it yielded. Often it is difficult or impossible to re-develop the small muscles by voluntary exercise alone; this applied especially to those cases which had been re-postured by surgical means, so that they were suddenly relaxed after a long period of overstretching with its accompanying atony.

SECTION OF LARYNGOLOGY.

A MEETING of this section of the Royal Society of Medicine was held on Feb. 4th under the presidency of Dr. W. JOBSON HORNE.

Tumours of the Ventricle and of the Ventricular Band of the Larynx.

The PRESIDENT, à propos of a case of supposed prolapse of the ventricle of the larynx shown by Dr. Frederick Spicer at the last preceding meeting of the section, gave an instructive epidiascopic demonstration on some cases of tumours of these parts which he had collected over a long experience of post-mortem examinations, with the object of contributing to the discussion as to whether prolapse of the lining of the ventricle ever occurred. He did not enter into the question of malignant tumours. In the first of the specimens the ventricle was occupied by a dependent growth. On cutting the larynx through, the growth was found to occupy almost the entire length of the ventricle. That tumour might eventually appear at the mouth of the ventricle and suggest prolapse, in spite of its being merely a supernumerary ventricular band. The second specimen (which was exhibited in spirit) was one of genuine prolapse of the lining membrane. There was necrosis of cartilage at the site of an old gumma, the epiglottis and aryepiglottic fold were considerably swollen, setting up real œdema of the larynx. The ventricle was occupied by the prolapsed membrane, and the prolapse came about through the cartilage necrosing. The lining membrane had become detached and had dropped out, and could be seen lying over the cord. The man was so desperately ill that he died practically on arrival at the hospital, before tracheotomy could relieve him. Other sections were shown in the series.

Dr. F. SPICER reported that when a portion was removed from his case the inflation collapsed entirely. —Dr. W. HILL showed a sketch of Dr. Spicer's case as it was seen by him. The sacculus laryngis perforated the false ligament and pushed the membrane of the ventricular band in front of it. When it collapsed it lay on the anterior part of the ventricular band. He regarded the case as one of sacculus laryngis.

Eversion of Sacculus Laryngis.

Dr. IRWIN MOORE demonstrated, by means of the epidiascope, two authenticated specimens of eversion of the sacculus laryngis, pointing out the need for discriminating between eversion of the sacculus laryngis and eversion of the ventricle. He contended that there was no such condition as prolapse of the ventricle, but it could be simulated by a tumour behind the ventricle pushing it forward.

Sir JAMES DUNDAS-GRANT considered that the appearance presented by Dr. Spicer's case when he examined it could only have been produced—with such a history —by a lesion beneath the vocal cord, at a spot where trauma had occurred, and air had been forced through this and through the submucous tissue of the vocal cord and the ventricular band. He gave his reasons for the belief. With regard to prolapse of the larynx, he agreed that every patient with that condition was tuberculous. He believed prolapse of the saccule of the ventricle could exist. — Sir STCLAIR THOMSON repeated his disbelief in the existence of prolapse of the ventricle of the larynx. Sir Morel Mackenzie, in his vast experience, evidently had not seen a case of it. Kocher cut sections in 19 cases of the supposed condition in Vienna, but did not find real prolapse in any.—The PRESIDENT said it was generally agreed that in speaking of the ventricle the sacculus was included. The eversion Dr. Irwin Moore spoke of did occur.

Tongue Adhesions.

Mr. NORMAN PATTERSON showed a bookbinder, aged 22, who five years ago had difficulty in swallowing and received treatment for "swollen larynx." It was not painful. A year ago he had treatment for lupus of the skin of the nose; he also had nasopharyngeal obstruction. Adenoids and tonsils were removed at 6 years of age, and since 9 years he had had skin lupus following trauma. He now had dyspnœa on exertion. Numerous bands of scar tissue could be seen in the oropharynx, extending to the base of the tongue in the region of the lingual tonsils. Wassermann reaction was negative.

Mr. G. W. DAWSON referred to two young cases of adherent palate. The complaint was of deafness and the discomfort of retained secretions in the nose. They were found to have congenital syphilis. Operations failed to maintain an opening, and recourse was had to an artificial palate, which was a success.—Sir WILLIAM MILLIGAN suggested that the present case might be one which sprang from unrecognised diphtheria, and the lupus might also have had an influence on it. Treatment of these cases he had found to be very unsatisfactory.

Fatal Tonsillectomy.

Dr. MCLEOD reported the cases of patients aged 10 and 6 years, girls, who died shortly after removal of their tonsils. For each the anæsthetic was C_1E_3. The first patient was quite well at 2.30, but two hours later was vomiting bright blood, and also one and a half hours later still. There was a blood clot in the naso-pharynx, but none in the tonsillar fossæ. Various procedures, including stitching of the faucial pillars, left the child improving and without bleeding, and at 10 P.M. she was talking. At 3 A.M., however, death suddenly occurred. In the second case the operation was done at a school clinic at 10.30 A.M. At 12.30 Dr. McLeod was called to the case on account of hæmorrhage and vomiting. As it had not ceased at 1 o'clock the anæsthetic was again given and the left fossa stitched and the naso-pharynx plugged. There was a clot in the left fossa. Consciousness did not return, and the end came at 5 P.M. The plug was firm in the naso-pharynx and there was no bleeding. Prolonged artificial respiration, injection of ether and strychnine, and heart massage failed to restore animation. Dr. McLeod sought information on the probable cause of death in these cases.

In the discussion on the cases attention was directed to the amount of blood which might enter the stomach from mere oozing without any bleeding vessel being specially identified. A case was mentioned in which a tuberculous gland had ulcerated into the carotid artery, and if that child had been put on the table for removal of adenoids the operation would have been blamed for a fatal result. Importance was also laid on the surgeon assuring himself that the bleeding had ceased before the patient was taken off the table. Acute acidosis was suggested as a possible cause of death. One speaker referred to only 5 deaths in 14,700 cases of this kind, ethyl chloride having been the anæsthetic. All the speakers commended Dr. McLeod on his courage in reporting the cases and seeking help for future guidance.

Osteomyelitis After Intranasal Operation.

Dr. DAN MCKENZIE showed a man, aged 29, on whom an intranasal operation on the frontal and maxillary sinuses was performed 12 months ago. A fortnight later an abscess formed at the inner angle of the corresponding orbit, and was opened by an external incision. The disease spread to parts of the face bones, and was checked by free removal of the infected bone areas. During the illness an autogenous vaccine was tried, but was discontinued, as it was causing severe focal reaction. The intravenous use of argentum colloid, however, produced great benefit. Convalescence was checked by acute rheumatism. The residual facial deformity is but slight.

Mr. W. M. MOLLISON offered his congratulations on the case, and spoke of the obstinate character of the condition in many instances.

Large Growth of Nasal Septum.

Mr. HERBERT TILLEY showed a woman aged 42, who had had a swelling on the right side of the nose eight months. An operation was done eight months ago, and was followed by a rapid recurrence of the growth and bleeding from the nose. Two months ago a large fungating mass projected from the right nostril. At the operation on that date the growth was seen to be attached to the septal cartilage by a pedicle one-sixth inch in diameter, and the swelling extended upwards and backwards to the ethmoidal region. Sarcoma seemed the most likely diagnosis.

Webbing of the Larynx.

The PRESIDENT showed a case of web in the larynx, the like of which neither the exhibitor nor any of the members present had ever seen.

Dr. A. LOGAN TURNER showed water-colour sketches of a number of diseased conditions, with notes of the cases portrayed.

Other cases were shown for diagnosis and were discussed.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.

AT a meeting held on Feb. 3rd Dr. W. LANGDON BROWN read a paper on

Types of Glycosuria and their Treatment.

He said that although carbohydrate forms more than 70 per cent. of the ordinary diet it only constitutes about 1 per cent. of the body-weight. This simple consideration showed that it is the most easily metabolised of the foodstuffs, so that disturbed metabolism is apt to show itself particularly in respect of carbohydrate. That true diabetes implied a great deal more than a mere disturbance of carbohydrate metabolism was now recognised; it was a disease characterised by exaggerated katabolism, which shows itself first and most obviously in respect of carbohydrates. Dr. Langdon Brown discussed the various ways in wh the body normally dealt with carbohydrates, and po out that it attempted to compensate for an imp power to assimilate them (1) by storing more usual as fat in the earlier stages of metabolism; (2) by raising the "leak-point" for sugar, thus diminishing its escape. He said that in some persons the leak-point is abnormally low, constituting renal glycosuria, which can usually be recognised by the constant output of sugar, irrespective of diet. Since the sugar in the blood and in the urine do not run parallel owing to variations in the leak-point, it is important to know what is happening in the former. A single observation is not of much use; it is far more helpful to give a dose of sugar and watch how the body is able to dispose of it by estimating the blood sugar at regular intervals. Adopting this method, Mackenzie Wallis had shown that the blood sugar followed an entirely different curve in different types of the disease. Dr. Langdon Brown demonstrated a number of curves which indicated the help that could be given in prognosis and treatment by this means. Some of these illustrated renal glycosuria, others the response of normal individuals. A series of curves were shown from mild, intermediate, and severe cases, illustrating the gradual approach of the curve to the severe type in which hyperglycæmia might be present even without glycosuria, but in which the administration of sugar was followed by an abnormally steep and sudden rise with a great delay in the fall. An interesting point was that the glycosuria of pregnancy followed the same type of curve as that due to thyroid or pituitary excess, confirming the view that it is due to the stimulating effect of pregnancy on these glands. Dr. Langdon Brown discussed the help which these curves gave in adapting treatment to individual cases, ensuring that these would neither be under-treated nor over-treated. He then considered the influence of alimentary rest, and said that something intermediate between Allen and Graham's plan would in the future probably be found to give the best results. Unfortunately, alimentary rest could not affect the underlying disturbance of the sympathetic nervous system, which he believed to be present in all severe cases, but could only deal with the result as expressed in the exaggerated katabolism. Therefore, carbohydrate tolerance sometimes continued to fall despite such treatment. Nevertheless, in other cases the damaged mechanism was able to show some degree of recovery through not being overtaxed, and certainly alimentary rest gave a more hopeful outlook in the treatment of diabetes than had existed previously.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

Exhibition of Cases and Specimens.

A clinical meeting of this society was held at the West London Hospital on Feb. 4th, Dr. F. J. **McCann**, the President, occupying the chair. The following cases and exhibits were shown:—

Dr. F. S. **Palmer**: A case of Progressive Muscular Atrophy (Aran-Duchenne type) in a man of 73. The disease was advanced, though symptoms had been present only 14 months. The whole right arm was markedly wasted and flail-like, with vaso-motor changes in the hand. Wasting was most evident about the shoulder. The left arm was affected to a less degree. Fibrillary tremors were present. Sensory changes were absent.—In reply to Dr. J. **Brindley-James**, Dr. **Palmer** said he was treating the case by electrical stimulation of the affected muscles and a strychnine tonic, but he did not know of any form of treatment that had any real influence on the course of the disease.

Dr. Arthur **Saunders**: A case of Facial and Lingual Hemiatrophy of Congenital Origin, in a girl. The auricle was malformed, though hearing was normal. X rays showed defective development of the cranial bones on the affected side.—Dr. **Palmer** remarked that alopecia was usually present in these cases on the affected side and was absent in this case.

Mr. **Aslett Baldwin**: (1) A case of Rodent Ulcer of Nose and Cheek treated by excision and plastic operation.—Mr. **Bishop Harman** cited cases of similar ulcers which had invaded the orbit necessitating exenteration of the orbit, and pleaded for early excision of ulcers of this type. (2) A case of Syphilitic Aneurysm of the Subclavian and Axillary and perhaps also the Innominate Arteries, noticed first two [illegible]hs ago. Pain was entirely absent. (3) A case with [illegible]ing of Uncertain Origin over the Scaphoid Bone of the Foot of three years' duration. An X ray plate of the foot was shown.—Mr. O. L. **Addison** expressed the opinion that the condition was certainly of inflammatory origin as shown by the skiagram. (4) A case of Multiple Enchondromata of the fingers after operation. X ray plates were shown to illustrate the condition of the parts.

Mr. **Bishop Harman**: A new Direct Record Scotometer which he had recently designed.

Mr. B. **Sangster Simmonds**: (1) A case of gunshot wound of the brachial plexus (complete lesion) treated by secondary suture. Operation was undertaken eight months after the injury. Sixteen months later there was some voluntary contraction in deltoid and biceps, with regenerating sensation. At present the deltoid, biceps, triceps, supinator longus, and extensores carpi radialis longior and brevior contracted voluntarily. (2) A case of Right Hemiplegia with Cortical Hemianæsthesia and Aphasia following gunshot wound of left parietal region. Patient was unconscious for three months. At present (30 months after injury) there was diminished but not complete loss of tactile, pain, and thermal sensations on the right side, while stereognosis and position sense were completely lost. Localisation was poor on this side. The hemiplegia and aphasia were recovering. (3) A case of Complete Lesion of Median and Ulnar Nerves of gunshot origin. A graft had been done from the internal cutaneous to the ulnar without success. The median nerve had been sutured a year ago. Mr. Simmonds said he proposed excising the ulnar graft and suturing the ends directly and bringing the nerve in front of the condyle. (4) Two cases of Gunshot Lesions of the Musculo-spiral Nerve. In one a 4-inch gap had rendered end-to-end suture impossible. Mr. Simmonds had 20 months ago performed tendon transplantation at the wrist. The man had now a useful hand with which he could earn his living as a clerk.—Mr. **Baldwin** wished to congratulate Mr. Simmonds on the excellent series of cases he had shown, and drew attention particularly to the last case in which a crippled limb had been restored to practically normal function.

Dr. D. G. **Rice-Oxley**: A case of Advanced Osteo-arthritis in a woman. There was no obvious source of infection, and all the usual remedies had proved ineffective. He had recently treated her with rheumatic phylacogen.—Dr. **Vaughan Pendred** cited a case in which he had found phylacogen of great benefit.—Dr. A. **Lapthorn Smith** asked if any members had experience of colloid sulphur.—Dr. **Rice-Oxley** said sulphur had not been used in his case.

Dr. J. **Burnford**: (1) A case of Complete Lesion of the Fifth Cranial Nerve of Tertiary Syphilitic Origin in a woman of 63. The condition was improving under specific treatment. (2) A case of Aneurysm of the Aortic Arch and Innominate Arteries. "Tracheal tugging" and "chin-jerking" were present. No laryngeal paralysis was present. (3) A well-marked case of Acromegaly in a woman. Symptoms had been present nine months.—Dr. **Lapthorn Smith** referred to the importance of "tracheal tugging" as a sign of aortic aneurysm.—Dr. **Rickard Lloyd** drew attention to the inequality of the pupils in the case of acromegaly.

Mr. **Tyrrell Gray**: (1) A case of Median Hare-lip, with marked lobulation of the tongue and a cleft of the soft palate of irregular form. (2) A case of Dupuytren's Contracture of Both Thumbs in a woman of 72, by occupation a cook. The condition was most marked in the right thumb. (3) A Sebaceous Horn of the Abdominal Wall which had recurred after removal of horn alone.

Dr. **Reginald Morton** showed an X ray of the chest of a diamond-miner suffering from silicosis. He pointed out the difference in the X ray appearances between this condition and pulmonary tuberculosis.—Dr. **Saunders** referred to the frequency of tuberculosis in the subjects affected by silicosis.

Dr. S. D. **Clippingdale** showed a Walking-stick, said to be 200 years old and now in possession of the Faggo family. It was of the type used by medical men of that period, and in its hollow handle and shaft were contained a phial and measuring-glass.

Manchester Royal Infirmary.—The annual report of the Manchester Royal Infirmary states that the total number of persons treated in all departments was 57,210—11,550 in-patients, 44,071 out-patients, and accident cases. The expenditure has increased to such an extent that but for a large donation from the National Relief Fund, which will not recur, and the disposal of £30,000 invested funds, the expenditure would have exceeded the income by £40,000. In order to induce the right type of women to take up the occupation of nursing, better salaries must be given and hours shortened. An additional income of £12,000 a year will be required for the maintenance alone of the staff in the nurses' home, which is to be erected near the infirmary at an estimated cost of £96,000. It is anticipated that during the next three years a total deficit of £200,000, involving the exhaustion of all funded capital, will have to be faced.

Reviews and Notices of Books.

TRAITÉ PRATIQUE DE SÉROLOGIE ET DE SÉRO-DIAGNOSTIC.

By MARC RUBINSTEIN. Paris: A. Maloine et Fils. 1921. Pp. 414. Fr.22.

THE author of this book disarms criticism at the outset by pointing out how impossible it is nowadays to keep abreast of research work in serology. Every laboratory worker who has made the attempt will heartily agree with him. One of the difficulties appears to be the interchange of foreign journals. We have reviewed more than one foreign book recently in which British and American work has been scantily considered, and doubtless there are English publications of which a foreigner might make a similar criticism.

The book before us is largely the outcome of an inquiry made by the author into the serology of syphilis, on behalf of the French Government. Consequently, the portion which deals with this subject is the most extensive; in fact, the discussion of the practical laboratory side of the serology of syphilis and cognate matters accounts approximately for one-third of the book. Dr. Rubinstein has evidently approached this side of the work with great enthusiasm, and has made investigations on collateral subjects, such as standardisation of complement, the variations in normal complement, and the "index de la sensibilisatrice." With considerable care he has also studied in detail most of the methods used for the Wassermann reaction, together with the well-known modifications which have been introduced from time to time.

The first part of the book discusses general questions, such as the examination and standardisation of antigens, the action of antibodies, and physico-chemical problems related to them. All these points are dealt with in a practical straightforward manner. There is little theory, and the more academic side of immunity, such as anaphylaxis, is only mentioned in so far as it relates to serum diagnosis. The last part of the work treats of serum diagnosis as applied to enteric, cholera, gonorrhœa, plague, tuberculosis; and closes with special chapters on the serum diagnosis of carcinoma and the Abderhalden reaction. With the treatment of these subjects the author has not, in our opinion, been so successful. There is no reference to the work of the American serologists on the pneumococcus, or to similar work on the meningococcus by A. Flexner and H. M. Gordon, and the workers of the Medical Research Council; again, there is very little reference to work on tuberculosis published since 1914, especially American work on complement-fixation. No doubt much of this was unavoidable owing to the difficulties of the war, but in some cases well-established pre-war work is omitted. In conclusion, therefore, we cannot help feeling that the author would have been well advised to confine his book to the serology of syphilis, of which he has evidently made a thoroughly able study, rather than to include other diseases in which he has not been able to bring his subject matter up to date. Dr. Rubinstein is to be congratulated on the excellence of his reference work as far as French and German authorities are concerned. This will be most helpful to English readers, but we cannot help regretting again that he has not included more references to good and reliable British and American research work on serum diagnosis.

MEDICAL ELECTRICITY.

By the late Dr. LEWIS JONES. Eighth edition. Revised and edited by L. W. BATHURST, M.D. London: H. K. Lewis and Co., Ltd. 1920. Pp. xvi. + 575. 22s. 6d.

THE present edition differs from those which have preceded it by the omission of the chapter on the Rontgen rays, and the addition of a new chapter on ultra-violet radiation. The subject of radiology has become so large that it cannot be adequately treated in a book devoted to electrotherapeutics. The effects of X rays are, however, described, and in the chapters dealing with treatment references are frequently made to their use for various diseases. In the chapter on ultra-violet radiation the experience of many recent workers in the use of the tungsten arc lamp is incorporated. Among other additions is an account of some work by Adrian on the measurement of the current that will cause contraction of normal and paralysed muscle when the duration of its flow is varied, the results being plotted in the form of curves. The editor is apparently not tempted to discuss the significance of these curves or to speculate on the part which the measurement of the chronaxie may play in the testing of the reactions of muscle and nerve.

Students of electrotherapy who are not familiar with the work of the late Dr. Lewis Jones would do well to read this book, as it contains the experience of one who was not only master of his subject but was a sound and safe teacher of a branch of therapeutics in which exaggerated claims and fantastic theories are too often presented, and are likely to mislead the beginner. The editor has done good service by his survey of recent literature and the addition to the book of the experiences of other English and foreign writers. Readers are thus acquainted with the work which has been done during the past two years on electrotherapy and electro-diagnosis. The treatment of the genital tract in the female might with advantage have been more fully considered. The present edition contains a more complete index than did its predecessors.

GENERAL PRACTICE AND X RAYS.

A Handbook for the General Practitioner and Student. By ALICE VANCE KNOX, M.B., B.Ch. With Chapters on the Production of X Rays and Instrumentation, by ROBERT KNOX, M.D., C.M., M.R.C.S., L.R.C.P. London: A. and C. Black, Ltd. 1921. With 32 page plates and 56 diagrams. Pp. 214. 16s.

IN spite of a declaration in the introduction that this handbook is written particularly for those who already realise the value of X rays, the text is chiefly occupied in emphasising in general terms the value of X rays in the diagnosis and treatment of disease. The reader will look in vain for concise information in regard to the preparation of the patient, his examination, or the reading of the radiograms produced. In the preparation of a patient for a barium meal it is advised to give a "good aperient" two nights before, a "mild aperient" the night before, and an enema on the morning of examination, which preliminary treatment would in most cases produce an unphysiological condition of the alimentary tract. The relation of the normal or abnormal stomach to the umbilicus is not given, nor is it mentioned that the patient should be examined standing as well as recumbent. Other matters are dealt with in a manner that suggests a writer who realises the value of radiography, but has little knowledge of its use. There is no reference to radiography of the teeth. The plates are very good and excellently reproduced. Part 2 gives a slight introduction to radiology and description of some of the apparatus in use, but the reader would require a knowledge of physics to gain instruction by reading it.

WHITE AND MARTIN'S GENITO-URINARY SURGERY.

Twelfth edition. By EDWARD MARTIN, BENJAMIN THOMAS, and STIRLING MOORHEAD. London and Philadelphia: J. B. Lippincott Company. 1920. Pp. 928. 35s.

IN the preface of this book the authors state that since their last edition the text has been revised and new illustrations been added, together with a special section on the prophylaxis of venereal disease. It is difficult to find any of these changes with the exception of the latter, incorporated in a useful article, although rather short. The book covers the whole of genito-urinary diseases and is essentially practical; the attention paid to differential diagnosis is especially valuable to the practitioner. More information might be given in future editions with regard to the methods and treatment of bladder papillomata by diathermic cauterisation: this is becoming a universal form of treatment, but is dismissed in a single sentence. The description of the various stages in the treatment of venereal disease is admirably full. The illustrations are, on the whole, excellent, but the reproduction of X ray photographs is still somewhat disappointing, as in the previous edition. The fact that the book has gone into 12 editions is sufficient evidence of its use.

MEDICAL NOTES.

By Sir THOMAS HORDER, M.D. Lond., F.R.C.P. Lond. London: Henry Frowde and Hodder and Stoughton. 1921. Pp. 112. 6s.

IN this little book, written in the form of clipt paragraphs, Sir Thomas Horder gives some of the results of a great experience of clinical and academic medicine. The book claims interest from every student and practitioner of medicine, and the material gives evidence of having been carefully filtered before it was allowed to crystallise into its present form. It is written, necessarily, in disjointed paragraphs, but a single idea runs through it and gives it sequence and uniformity. The "Notes" centre round diagnosis; the first proclaims its paramount importance, but nevertheless due place is found for treatment and prognosis. Diagnosis depends on physical signs, for "one physical sign is of more value than many symptoms," a point worth remembering at the present time, when some would appear to believe that symptoms always develop before signs of disease. Many "Notes" show the minute care taken in eliciting physical signs, while perhaps the most refreshing current running through the text is the critical appreciation of the value of the observed signs and of the limits to the deductions to be drawn from them. There is obvious courage in an author who gives the world a clear insight into his practice of medicine and who lays himself open to criticism by dogmatic statements. That some of the statements, which bear the sure stamp of originality, are the commonplace of current text-books is no criticism of these "Notes," but it is pleasant evidence that text-books themselves are ultimately based on personal experience. Though the "Notes" have no doubt been jotted down at any moment that they took form in the author's mind, yet the subjects dealt with preserve a certain proportion. Common diseases and conditions are recognised as more important than the uncommon; the "tripod of life," the heart, lungs, and brain, claims 72 pages of the total 112, evidence, were it needed, of the well-balanced mind of its author.

IN SEARCH OF THE SOUL.

The Mechanism of Thought, Emotion, and Conduct. A treatise in two volumes. By BERNARD HOLLANDER, M.D. Vol I., The History of Philosophy and Science from Ancient Times to the Present Day. Vol. II., The Origin of the Mental Capacities and Dispositions of Man and their Normal, Abnormal, and Supernormal Manifestations. London: Kegan Paul, Trench, Trübner, and Co., Ltd. Vol. I., pp. 516; Vol. II., pp. 361. £2 2s. complete.

ABOUT one hundred years ago a certain Mr. Robert Montgomery wrote some singularly bad poems, in one of which occurred the couplet, damned for ever by Macaulay:—

> The soul, aspiring, strives its source to mount,
> As streams meander level with their fount.

Montgomery's absurdity must have exercised some influence upon Dr. Hollander's unconscious mind, for just as Montgomery's soul strove for an absolute impossibility (no stream can, or ever could, "meander level with its fount"), so Dr. Hollander comes to this conclusion at the end of his second volume: "It would be audacity on my part to affirm or deny, or even to argue, on the existence of a soul and a life hereafter. Not until investigations are made on the lines described in this work, not until ethology is recognised as well as psychology, not until brain research is extended from motor and sensory to mental manifestations ...... will it to speculate on the soul and spiritual nature Only one suggestion I would venture in conclusion. Every particle of man is alive and adjusted in its function to the whole being, the self, and by his thought and emotion he can control not only his brain activity but every function of the body, accelerating or inhibiting it. From this it appears to me that instead of saying, 'man has a soul' it would be more correct to say that 'man himself is a soul.' He is not a conscious machine, but a spiritual being." However, although Dr. Hollander ends with the same note as Ecclesiastes, his two closely printed volumes contain an enormous amount of information, and the first volume in particular is most useful as a book of reference. We have noticed a slip or two—for instance, he makes no mention of the Minoan civilisation, and on p. 121 the date of John of Gaddesden's notes on travel is given as 1350 instead of 1305, which it probably was, and no one would gather from his notice of Weyer (Wierus) that he was much in advance of his time in writing on the folly and cruelty of trials for witchcraft. Nearly 200 pages of Vol. I. are devoted to an account and examination of Gall's life and work and point out what is generally unknown or overlooked—viz., that Gall was not so much a phrenologist as a great anatomist, physiologist, and psychologist. Vol. II. is mainly concerned with ethology, or the science of character, and the cerebral origin of intellectual operations. Dr. Hollander pleads, and rightly so we consider, for early and individual treatment of mental cases (pp. 241–242). The book as a whole is a useful contribution towards the study of a very obscure subject, though here and there it has its longeurs, and the very close print makes its reading for any length of time somewhat difficult.

PROTHÈSE DENTAIRE.

Third edition. By MAURICE WISNER. Paris: Libraire Le François. With 55 illustrations. 1920. Pp. 224. Fr.12.

THIS book, which, according to the preface, is intended for practitioners and not students, contains information dealing with the rudiments of dental mechanics. Some of the author's ideas are a little out of date—for example, the suggestion that crowns should be fixed with silk and mastic varnish. The author advocates the removal of a plaster impression before it has quite set, a plan which cannot fail to produce defectively fitting dentures. Dental mechanics is too large a subject to be dealt with efficiently in such a small work.

THE SCIENCE OF OURSELVES.

A Sequel to the "Descent of Man." By BAMFYLDE FULLER. Oxford Medical Publications. London: Henry Frowde and Hodder and Stoughton. 1921. Pp. 326. 16s.

THIS pleasant book, by one who has seen much of the world in different continents, centres round the proposition that, as man's bodily characteristics have evolved from those of the lower animals, so his mind must also have developed in much the same way from a simpler state. Consciousness, and that awaredness of consciousness which is the outstanding property of the human mind, must have evolved from the unconscious, and by a study of the different "planes" on which the nervous system acts the author seeks to show how this may have come about. He never really faces up to the question whether the mind is a product of the brain or whether the brain is, as James would say, a window which lets something in from outside; but it is evident that while he would have preferred the latter conclusion he feels that the evidence compels him to accept the materialistic interpretation. And in this there is some encouragement: man is a disappointing angel but an astonishingly good ape, and if we realise that anger, pride, and jealousy are merely nervous reactions without any particular nobility of origin we are the better able to resist them. The other great problem, whether elementary animals have "minds" and "souls," is not brought under close survey. Like most people who are interested chiefly in human affairs the author roughly assumes that they have not; if he had been a naturalist with the same shrewd kindly outlook on worms and insects as he has on his fellow-men he would probably have held the opposite view. It is doubtful whether the book can be classed as a great contribution to the understanding of the nervous system or of the mind, but it will do most people good to read it and follow out for themselves some of the many lines of thought which it will suggest. There is an interesting note on Indian "wolf-children," the genuine occurrence of which is regarded as substantially authenticated.

Selected Materia Medica.

By W. C. Sillar, M.D., B.Sc., and C. G. Lambie, M.B., Ch.B. Edinburgh: James Thin. 1920. Pp. 41. 2*s*. 6*d*.

Here we have a series of interleaved tables whose purpose is to render more simple the memorising of the pharmacological actions, therapeutic uses, and doses of drugs, the material dealt with having been chosen with a view to eliminating "the redundancy of the official list." The following tables are among those included: a list of the English names of drugs arranged pharmacologically, with average metric doses and Latin abbreviations, which, by the way, are not always identical with the official ones; drugs and preparations for oral administration, arranged according to dosage, but subdivided into certain fairly well-defined groups; and various tables of drugs and preparations applied externally or given by injection, inhalation, and so forth, with the strengths of the preparation so employed. About a page is devoted to prescription writing, and some information is given as to the dosage of sera and vaccines. It will be gathered from the foregoing that the volume falls into that class of books which, when judiciously used, are helpful for purposes of revision and rapid reference; but our advice to the student is that he should, if possible, himself compile such synopses, of which he will then realise the limitations, from standard works and lecture notes. He will not fail to acquire much valuable knowledge in the process.

JOURNALS.

Journal of Laryngology and Otology.—The January issue of this journal, formerly the *Journal of Laryngology, Rhinology, and Otology*, contains, under the title Chorditis Fibrinosa, an interesting paper by Dr. A. Brown Kelly. He describes an uncommon variety of acute laryngitis characterised by the deposition of fibrin and the occasional formation of erosions on the vocal cords. All his cases occurred amongst soldiers, and he comments upon the obvious rarity of the affection in civilian life. The irritating effect of gas was the commonest cause assigned for its production.—Dr. Irwin Moore gives the first instalment of a paper upon Angeiomata of the Larynx, a variety of tumour sufficiently rare to merit the labour which he has expended upon collecting all the references to it in literature.—Dr. J. Kerr Love contributes a Critical Review upon Deaf Mutism, a subject upon which he is well entitled to write. He emphasises the important point that it is the duty of the medical man to search for the causes of deafness and to apply this knowledge to its prevention. In the hands of the new management, the general appearance of the journal, as regards paper and type, has been much improved.

Brain. Vol. XLII., Part 4.—Suggestion and Suggestibility, by E. Prideaux. The author defines suggestion as "a mental process resulting in the acceptance with conviction of a proposition in the absence of logically adequate grounds for its acceptance." The chief factor in the process is the suggestibility of the patient. Four forms of this are differentiated: (*a*) Individual, (*b*) conditional, (*c*) specific, (*d*) personal. All come into play in the process of suggestion; they are "affective states evoked by the stimulation of different instinctive tendencies." Depending upon the relationship of the suggested idea to the several forms of suggestibility, three types of response are possible: (1) Positive, (2) negative, (3) neutral. An idea is accepted because it harmonises with some preformed interest, sentiment, or complex; a negative response results when the idea is not in harmony with these—i.e., "negativism" is marked; the response is neutral either when there are no preformed complexes to which the suggestion can attach itself or when there is a conflict of motives with the production of a state of doubt. Hypnosis is to be regarded only as an exaggerated form of suggestion. The aim in treatment is to induce suggestibility in its various forms in the patient; the affective state may be altered by inducing an emotion of surprise or anger. "There is no question that the method of normal suggestion by explanation and appeals to feelings is the best. ...... In the other methods the patient relies entirely on the physician, does not understand his condition, and is much more likely to relapse."—Lethargic Encephalitis; Its Sequelæ and Morbid Anatomy, by E. Farquhar Buzzard and J. G. Greenfield. 20 cases and the pathological findings in five fatal ones are recorded. The symptomatology is much more varied than was at first believed. It is suggested that the characteristic lethargy may be attributed to blockage of the iter by inflammatory œdema of the region of the corpora quadrigemina. There are three main types of case: (1) with hemiplegia, &c.; (2) resembling paralysis agitans, the basal ganglia group; (3) with implication of the cranial nerves. But the lesions are always more widespread than the main symptoms suggest. A striking feature of the more serious cases is the late development of involuntary movements of the limbs, jaw, or tongue. The authors consider that probably "they represent the release of some nervous activity by interference with control." The only treatment advocated is re-education of control, and the prognosis is favourable. Four cases in people over the age of 40 are described, from which the following important lessons are to be learned: (1) that patients over 40 may be the victims of encephalitis, producing hemiplegia, &c.; (2) when there are no obvious gross signs of disease in the cerebral arteries to account for a hæmorrhage it is essential that microscopical investigation should be carried out; (3) the presence of thrombosed cortical veins associated with hæmorrhage in the neighbouring brain substance is strongly indicative of an inflammatory process. The microscopical features are vascular congestion, toxic degeneration of nerve cells and neuronophagy, proliferation of the mesoblastic cells of the vessel walls and infiltration of the nervous tissue by these cells, small-celled infiltration of the Virchow-Robin space, glial proliferation. Venous thrombosis and hæmorrhage are not uncommon; the latter occurs round a congested vessel, usually a vein, or as a result of infarction from an arteriole.—Local Paralysis Following Superficial Injuries not Involving Nerve Trunks, with Special Reference to Traumatic "Ascending Neuritis" and to "Reflex Paralysis," by F. M. R. Walshe. Four cases are described which indicate that in rare instances the clinical manifestations of a local neuritis may follow trivial injuries of the afferent terminations of the nerve affected. The symptoms were progressive, but in only one case was there evidence of continued upward extension. The author considers that the cases approximate to the condition known as "ascending neuritis" rather than to the muscular reflex affection of acute arthritis and allied lesions; he suggests that a small proportion of Babinski's cases of "reflex nervous disorders" may have been of the same nature.

Vol. XLIII., Part 2, 1920.—Aphasia and Kindred Disorders of Speech, by Henry Head. In this, the Linacre lecture for 1920, the author puts forward a fresh conception of the clinical phenomena of loss of speech from the physiological rather than from the anatomical point of view. All previous theories fail to explain clinical facts. In particular, those presuming a localisable "faculty of speech" or the storing of "images" of movement, hearing, and sight give no explanation of the inconstant response to tests which is so characteristic in lesions of the cerebral cortex. The author has elaborated a new method of examination by "serial tests, which alone make it possible to draw any conclusion from the inconstant responses." Owing to the war it has been possible to apply the tests to men who, apart from their head injuries, were in perfect health, a very different type from the usual civilian aphasic. For a description of the tests the reader is referred to the original paper; any summary of them would be misleading, for they depend for their usefulness on the most minute observance of detail. As a result of this research the author is enabled to draw the following conclusions. Disorders in the use of language, due to a unilateral lesion of the brain, cannot be classed under the categories of isolated affections of speaking, reading, or writing. They cannot be explained as due to destruction of images. In cases of so-called "motor" aphasia not only external speech but certain aspects of internal verbalisation are affected. The gravest and most definite disturbance is to be found in the use of words, figures, and other symbols; the functions which are affected in aphasia and kindred disorders of speech may be grouped under the heading of "symbolic thinking and expression." and any act is liable to suffer which requires for its perfect performance the antecedent formulation of the ultimate intention or goal towards which it is directed. The more nearly a symbolic action approximates to a proposition the greater difficulty it will present. Lastly, under the influence of lesions situated in different parts of the brain the various functions comprised under "symbolic thinking and expression" may become dissociated into forms which may be comprised under the headings: (*a*) verbal aphasia, a defect of word formation; (*b*) nominal aphasia, a defective use of names and want of comprehension of the nominal value of words or other symbols; (*c*) syntactical aphasia, articulation of the word is ill-balanced, the rhythm of the phrase is defective, and there is want of grammatical coherence; (*d*) semantic aphasia (from *σημαίνειν*, to signify), a want of recognition of the full significance of words and phrases; the patient may understand each word or short phrase, but the ultimate meaning escapes him; he cannot formulate symbolically a general conception.—Congenital Familial Spinal Muscular Atrophies and their Relation to Amyotonia Congenita, by Knud K. Krabbe. Six cases of the former extremely rare condition are recorded, and the published cases of the latter subjected to a critical review. The author emphasises the "radical pathological differences existing between the heredo-familial diseases and other diseases." He considers that "the cases which have been described as amyotonia congenita represented really two different diseases: (1) Amyotonia congenita, a benign disease, which consists of a congenital hypotonia, hyperflexibility and weakness, but no atrophies. It is not familial and can possibly be considered as a retarded development of the muscles; (2) congenital familial progressive spinal muscular atrophy, a type most related to Werdnig-Hoffmann's disease, but congenital, and which bears a certain resemblance to amyotonia congenita clinically, but differs from it in that the muscles show a marked atrophy, demonstrable by the X rays, that it has a tendency to progression, or at any rate not to improvement, and in a certain number of cases it can be shown that the disease is familial.

Reports and Analytical Records

FROM

THE LANCET LABORATORY.

PURE GLUCOSE AND PURE ANHYDROUS GLUCOSE.

(BRITISH DRUG HOUSES, LTD., 22-30, GRAHAM-STREET, CITY-ROAD, LONDON, N.)

PURE glucose is extensively used in medical and surgical practice as an intravenous, subcutaneous, or rectal injection. It has been claimed that the substitution of glucose solutions for saline solutions is a step forward in therapeutics, since glucose solutions have no injurious action on the kidneys, and, in addition to a diuretic action, possess notable nutritive properties. An examination showed that the "pure glucose" had a specific rotatory power of + 52·3° (absolute), was free from mineral matter, and had the composition of the monohydrate $C_6H_{12}O_6+H_2O$. The "pure anhydrous glucose" had a specific rotatory power of + 53·2° (absolute), and is accurately described as anhydrous. It is prepared specially for use in bacteriological laboratories and as an excipient for hypodermic tablets. For the first mentioned purpose, however, we are of opinion that anhydrous glucose offers no advantages over the hydrate. It is satisfactory to learn that glucose of this high degree of purity, which prior to the war was a continental product, is now being manufactured in this country.

(1) OSCOL STIBIUM; (2) ASEPTOIDS: NASAL COMP.

(OPPENHEIMER, SON, AND CO., LTD., 179, QUEEN VICTORIA-STREET, LONDON, E.C.)

(1) This is a true colloidal preparation of antimony sulphide (Sb_2S_3), and it is stated to have been used with advantage in the treatment of bilharzia and leprosy. If this is correct the preparation may be found useful in other directions. On analysis we find that 3 parts of antimony sulphide are present in 2000, which confirms the statement that 1 part of antimony (Sb) is present in 2000. (2) These tablets are made from a formula supplied by the late Dr. H. Macnaughton-Jones, which is referred to in his latest work on diseases of the nose, throat, and ear. The ingredients are sodii chlor., sodii bibor., menthol, thymol, eucaine hydrochlor., ol. gaultheriæ, ac. boric et sodii benz. These are made into square-shaped tablets and are not compressed, so that when dissolved in warm water rapid solution is effected.

METAGEN.

(PARKE, DAVIS, AND CO., BEAK-STREET, REGENT-STREET, LONDON, W.)

This preparation is stated to contain the three types of vitamines—the fat-soluble A vitamine, which possesses antirachitic properties, the water-soluble B vitamine, which exerts a growth-promoting and antineuritic influence, and the water-soluble C vitamine, which is an antiscorbutic. The material is conveniently supplied in soluble gelatin capsules, each containing 5 gr. It is stated that metagen may be advantageously administered in cases of lowered bodily tone, subnormal nutrition, and in diseases arising from a lack of vitamines in the diet, such as scurvy, beri-beri, marasmus, malnutrition, &c. It is also applicable where it is desired to build up nutrition—e.g., tuberculosis, rickets, simple anæmia, chlorosis, and other blood diseases. Unfortunately, the activity of the vitamines cannot be expressed quantitatively by chemical means, the only methods available being physiological. Messrs. Parke, Davis, and Co. state that the efficiency of metagen has been widely tested in hospital and private practice, and the recommendations concerning the use and mode of administration of metagen are based on the reports of impartial clinicians.

"GADUS" VIRGIN COD-LIVER OIL.

(JOHN BELL AND CROYDEN, LTD., 76-80, KENSAL-ROAD, LONDON, W.)

Messrs. Bell and Croyden are the sole British agents for this oil, which is stated to be prepared in the Lofoten Islands, Norway, from the liver of the cod on the same day that the fish is caught. The oil when analysed was found to have the constants of a pure cod-liver oil, and it also responded to the customary chemical and B.P. tests. The iodine value was slightly lower than that usually found. The oil is pale-yellow in colour and is devoid of any unpleasant smell or flavour. The manufacturers claim that its low viscosity renders it less objectionable to the palate than the thicker oils, with the consequence that it is readily tolerated and does not repeat.

New Inventions.

IMPROVED GAS-OXYGEN-ETHER OUTFIT.

THE illustrations show some improvements that have been made for use with my gas-oxygen-ether outfit. Fig. 1 is an improved ether or mixture bottle comprising a three-way valve, below which is a perforated cup that can be raised or lowered upon the inlet tube inside the bottle. The tube is perforated in two places, the upper being inside the cup and the lower one below the cup. The open end of the tube makes a third aperture. A filling funnel is placed behind the valve. The advantages of this bottle are that the anæsthetist can graduate the amount of ether or mixture better than was possible with the older pattern, for with this bottle the gases can pass in three ways: (1) to the patient direct and without any ether; (2) over the surface of the ether or mixture, thus giving quite a small amount; (3) through the ether or mixture when the anæsthesia has to be deepened. Fig. 2 shows a nasal attachment comprising a metal stirrup to which are attached a couple of short soft rubber tubes. I have found this very useful for endobuccal and endopharyngeal anæsthesia, and especially for such cases as diathermy of the tongue or palate, or for œsophagoscopy and bronchoscopy. It is also very useful for some operations upon glands in the neck, enabling the anæsthetist to keep well out of the way of the surgeon. The rubber tubes should be about four inches long. The appliances are made by Messrs. Coxeter and Son, 171, Pancras-road, N.W. 1.

LONDON: SATURDAY, FEBRUARY 19, 1921.

Dermatology in Relation to General Medicine.

THE admirable address delivered before the Medical Society of London last Monday by Sir JAMES GALLOWAY on the relation of skin diseases to internal disorders, which we publish this week, sets forth very clearly the important part that the study of dermatology should take in the training of the general physician. There is a tendency even in these days to consider dermatology as a subject apart, and the average student of medicine is content if he can recognise the eruptions of the specific fevers, a typical case of scabies or ringworm, and a few other common skin diseases, such as psoriasis and impetigo contagiosa. He is not unnaturally appalled at the complexity of dermatological terminology, and when later he is confronted in practice with a skin eruption, which he may or may not recognise, he is inclined to ring the changes on a few ointments or lotions in the hope that one may eventually "touch the spot," without considering the possible connexion between the patient's skin and the general state of health. Yet, as Sir JAMES GALLOWAY aptly says, "the knowledge of external and visible signs may lead to the interpretation of their hidden cause, the recognition, it may be, of a mysterious malady, to its treatment, and the restoration to health of the sufferer." This, it seems to us, is the crux of the whole matter. It is difficult for the consulting physician, and quite impossible for the general practitioner, to become familiar with the rarer diseases of the skin or with the progress of dermatological research; but every student should be taught not only to recognise the commoner dermatoses, but also to interpret the cutaneous manifestations of internal disorders, such as errors of digestion, intestinal intoxication, and the like. He should be made to look at the skin as assiduously as he listens to the chest. That he does not do so is, we think, largely because he is taught dermatology from this wrong point of view: "Here is a patient with a dry scaly rash, the distribution is largely on the extensor surfaces, more particularly on the elbows and knees; the disease is, in fact, psoriasis, and we will order a tar or chrysarobin ointment and increasing doses of arsenic internally"—and that is all. He will be taught that we do not know the cause of psoriasis, but he will probably not be taught that every case of the disease should, if possible, be investigated as completely as if it were an obscure case in the medical wards, that it is important to know whether a patient with psoriasis has any symptoms or signs of rheumatoid arthritis, and that, if such be the case, foci of infection must be carefully sought for and treated, that a complete examination of the whole digestive system must be made, the urine tested for excessive acidity and for indican, and the blood, perhaps, for excess of sugar.

The tendency is, in fact, for the student to learn to label certain eruptions, and to associate with each a certain stock treatment, such as tar for psoriasis and chronic eczema, mercury for impetigo, and sulphur for acne, whereas, except in diseases of purely external origin such as ringworm and scabies, the majority of patients with skin disease require a complete medical examination. Conversely a great deal may be learnt from the appearance of the skin, its colour, the activity of its secreting glands or the presence of pigmentation, in cases of dyspepsia, neurasthenia, and chronic ill-health. This leads us to the consideration of the much debated question of intestinal toxæmia. It would seem that two main types can be recognised:—that in which there is abnormal fermentation of carbohydrate, and that in which excessive intestinal putrefaction occurs. The difference in appearance presented by patients of these two types is very striking. In the former the skin of the face, neck, ears, and scalp is flushed, the sebaceous and sometimes the sweat-glands are hyperactive, the lips are bright red and covered with a kind of scum, the tongue is firm and red, with prominent papillæ, and aphthous ulcers are sometimes present in the mouth. The gastric acidity varies. The urine is usually hyperacid, and as a rule contains no indican. Persons of this type are liable to acne and boils, and to acute seborrhœic eczema. On the other hand, the person in whom intestinal putrefaction is in excess corresponds to the description given by LANE of the sufferer from chronic intestinal stasis. The complexion is sallow; the lips have a bluish tint; the tongue is pale, smooth, and indented at the edges; there is pigmentation around the eyes, in the joint flexures and wherever pressure occurs on the skin, as from corsets; the extremities are blue and cold and in a state of clammy perspiration; and often these unfortunate patients emit a peculiarly offensive sour odour. The gastric acidity is almost always low, and there may be complete achylia. The urine nearly always gives an intense indican reaction. These patients are not uncommonly subject to recurrent attacks of pompholyx. We need not pursue this comparison further; it has been given merely to show that the skin is a mirror in which the state of a person's health may often be clearly visible.

As indicated by Sir JAMES GALLOWAY, the appearance of a cutaneous eruption is frequently the first available clue to the presence of some focus of infection. This is well illustrated by the group of eruptions to which DARIER has given the name tuberculides. As examples may be given the erythema induratum of BAZIN, and the papulo-necrotic lesions that occur on the distal parts of the extremities. These eruptions are evidently inflammatory reactions around tubercle bacilli brought by the blood-stream from some distant tuberculous focus, usually glandular, and coming to rest in parts where the cutaneous circulation is sluggish. The appearance of such lesions may be the first indication that a patient is suffering from active tuberculosis, although nearly all people who develop tuberculides exhibit the stigmata which betray a massive infection with tubercle in early life. In the same way erythema nodosum, and in some cases erythema multiforme, are reactions to a streptococcal infection. The early recognition of eruptions such as these, and of their significance, is obviously of great importance, in order that the patient may be submitted to an exhaustive examination, and be given the treatment necessary to combat the underlying infective condition which the cutaneous lesions have revealed.

Medical Education in China.

A SPECIAL meeting of the medical profession will be held on the afternoon of Monday next, Feb. 21st, at the Royal Society of Medicine, the object being to emphasise the developments which have been made in China in recent years in medical education—developments to which medical practitioners from the United States and this country have mainly contributed. To our readers the information that the profession of medicine is held in the deepest esteem in China will not come as news, for we have been able from time to time to keep them posted in things medical, as they occur in the vast Eastern Republic. Dr. WU LIEN TEH, physician extraordinary to the President of China, published in our issue of May 29th, 1920, a detailed account of medical progress in China since the establishment of the Republic, and especially since the issue of a Presidential mandate in 1915 recognising Western medicine as the proper course of medical practice in China. The *National Medical Journal of China* has brought the story up to date, a recent issue containing, in addition to a varied assortment of quite modern medical articles, an excellent essay by Dr. PETER C. KIANG, showing the keenness and devotion of the Chinese medical student to the calling which he has adopted.

The Republic of China is in a state of transition, so that all vocational education of a modern sort is complicated by the political situation. But the calling of medicine appears likely to be the first to establish itself on an organised basis, chiefly because a greater percentage of medical students than of students in any other faculty stick to the profession of their first choice, practising it faithfully after return from universities or professional schools to which they may have been attached abroad. This is a distinguishing feature of the medical student. Other students, on their return to China from abroad, are prone to change the direction of their work. Chemists and engineers go into the public services or into the employment of banks, and mining engineers drift into commerce; but the Chinese medical man, educated in Europe or America, on returning to his native land invariably practises medicine. And he does this, as many of our own medical men do, not because an easy or lucrative career is open to him, but because, having served his apprenticeship in medicine, no other metier seems worth following. The career of the Chinese general practitioner among his own people is attended with two main drawbacks which make general practice so often hard in this country —the life is physically a wearing one, and the public appreciation of medical efforts is capricious. Criticism, indeed, of the Chinese practitioner appears to be prompt and outspoken, for if a patient's temperature does not abate on the mere appearance of the doctor, the reason why is demanded severely. Public opinion therefore needs to be cultivated, and education of the public earnestly undertaken. But we may be certain that the fact of the medical students sticking persistently and faithfully to their profession, when they return from abroad, will prove a great public argument for a better appreciation of science. The Chinese are notoriously good and honourable men of business, and to them the recognition that medical men prefer their o [illegible] lling to any other, despite its drawbacks [illegible] ite invitations to easier careers, will form [illegible] proof that the rewards of a life with noble ideal are higher than those of an exclusively material objective, and that the calling must be a high one which obtains adherence on such a basis.

Modern China is ripe for the development of modern medicine. Medical learning in China has passed the first and difficult stage, and now it is necessary that the standards of medical education should be raised, and that hospital practice should be more generally based upon the science of to-day. Dr. HAROLD BALME's work, prepared under the auspices of the China Continuation Committee, a committee instituted to inquire into the scientific efficiency of mission hospitals in China, indicates a general consensus of opinion in regard to this matter. The institution of this committee, the fine housing of the China Medical Board, and the equipment of the Pekin Central Hospital and Union Medical College alike prove this. The pioneers of medical science in China have to face a considerable difficulty in laying out a medical curriculum for Chinese students, for whom it is necessary to have a bilingual system in medical nomenclature, with the attendant difficulty of securing an exact equivalent of meaning. But a good beginning is bound to have a fruitful issue.

◆

The Sanitary Authority and Encephalitis Lethargica.

As is well known, acute encephalitis lethargica has been a notifiable disease since Jan. 1st, 1919, and the number of cases notified in the administrative county of London is issued weekly on the authority of the Registrar-General and is recorded in our columns. One of the striking features in the interesting survey of the cases notified in Manchester during 1920, which we publish in our present issue, is that in not a single instance has the spread of infection from one person to another been traced. Not one of the 138 family "contacts" of the disease caught the infection. Dr. W. ST. C. MCCLURE makes the deduction that the disease is not infectious or that the infection is widespread and most people are immune. He, however, "hedges" by the suggestion that until our knowledge becomes more complete we ought to presume the disease infectious or contagious and take precautions accordingly. The fatality of the Manchester cases is very high. The diagnosis was confirmed in 32 cases, of which 17 proved fatal. Of the remaining 15 only 2 have made a complete recovery, 7 are still ill, and 6 at periods varying from two to nine months after the onset are seriously damaged. It seems probable from this high fatality that a considerable number of milder cases have been unrecognised. We believe that experience elsewhere confirms the Manchester experience as to the failure of the patient to spread infection, but that elsewhere the occurrence of a larger number of milder cases has been reported. The value of notification at present is chiefly the facilitation of investigation, and the Manchester Public Health Department, through its staff of medical assistants, has been in a good position to undertake such inquiries.

For most notifiable diseases there is a routine procedure—isolation of the patient, removal to hospital, and disinfection of the house. In the case of encephalitis lethargica, those who have had experience do not hesitate to treat patients in a general hospital. Nor can we see that it is justifiable, in view of the apparently non-infectious nature of the disease, to exclude "contacts" from school or work. Education is already much interfered with by diseases known to be infectious and we ought not to add another disease to the list without any evidence of its infectivity and simply because it is as yet a mystery. The tendency is rather to regard a mysterious disease as infectious. In Osler's Medicine, the edition published in 1901, it is mentioned that the leading Russian medical authorities at that time believed scurvy to be infectious, and Osler himself classified beri-beri among the specific infectious diseases. In these last years we understand these two diseases better. There is already too great a tendency on the part of the half-informed to create scares about new diseases and we must not pander to that tendency. Notification has its value no doubt as a means of putting the medical practitioner on the alert when he meets with obscure ailments resembling encephalitis lethargica, and of thus facilitating the patient investigation of its cause, but it cannot be said that, in the present state of our knowledge, notification enables the sanitary authority to take any practical steps for the prevention of encephalitis lethargica.

The Prince of Wales, F.R.C.S.

On the occasion of the birth of the Prince of Wales as third in direct succession to the Crown, a partly humorous but wholly loyal suggestion was thrown out in these columns that, having regard to the increasing part which things medical must play in future Imperial administration, his Royal Highness should be a medical man. The suggestion became a fact on Monday evening last, when at the Hunterian Festival Dinner his Royal Highness was admitted an Honorary Fellow of the Royal College of Surgeons of England. At the time of his birth the constitution of the College made no provision for Honorary Fellows, but in 1900, that being the centenary date of the reconstitution of the College under Royal Charter, the necessary powers were acquired, and the first Honorary Fellow thus admitted was the late King Edward VII. The present King, while Prince of Wales, graciously accepted the same diploma, and now the Prince of Wales has followed his father's and grandfather's suit, being elected among a group of six who have especially distinguished themselves in the war. The other five are the Duke of Connaught, Colonel-in-Chief of the Royal Army Medical Corps; Dr. Pierre Duval and Professor Antoine Depage, respectively selected to represent the medical work of our Allies, France and Belgium; and Brigadier-General J. M. T. Finney and Dr. Charles Mayo, respectively Chief Surgeon to the American Army in France and Adviser to the Army Medical Service in the United States. The Prince of Wales's right to inclusion in this distinguished group was justified fully by Sir Anthony Bowlby at the Hunterian Festival Dinner, when he described the Prince's work at the front as admirable, his personality to have acted throughout the war in all ranks as a source of inspiration, and his tour of the Empire to have been an unqualified success. The President obviously spoke out of conviction and not out of courtliness, and the Prince of Wales in his reply took the opportunity of paying a tribute to the service of medicine throughout the war in words which clearly had their origin in sights which he had seen and things which he had learned. The impressive part of a dignified ceremony was that it was the outward sign of genuine feeling.

Annotations.

"Ne quid nimis."

THE DISPOSAL OF DOMESTIC REFUSE.

An inquiry held by the Ministry of Health on Jan. 12th at Sheffield with regard to a proposal to spend £200,000 on a new method of disposing of the city's refuse has more than a local interest. The problem has its economic side and its sanitary aspect. It was shown that the total amount of refuse collected annually is about 130,000 tons from a population of about half a million. Putting aside the 20,000 tons from the privy middens, an incubus which must continue to be dealt with at the destructors till the privy middens are all converted into water-closets, the problem consisted of dealing with the contents of dustbins and so-called dry ashpits. Three methods were considered—viz., the reconstruction and extension of the destructors, tipping, and a special method of sorting and screening the refuse. It was shown that the capital cost of reconstructing and extending the destructors would be from £150,000 to £200,000, while the cost of burning the refuse at the destructors after collection would be equal to a shilling rate, or over £90,000 per annum. Tipping was ruled out largely on sanitary grounds. The tips would have had to be at a long distance from the city, and objection is always raised by the residents of the districts in which they are established. Besides the nuisance from rats, effluvia, paper being blown about, the firing of the tips, and so forth, the cost is always run up by the heavy transport charges.

The third method was the one selected. Plant of a size capable of dealing with the refuse of a population of 40,000 has been in use for some time, so that the method has already had a sufficient trial to enable reliable estimates to be made as to the cost of the process. The plant consists of electrically driven revolving screens, which sort the refuse into constituent parts according to the size of the mesh of the screen. The first material sorted out is a fine dust, about 33 per cent. of the whole, which passes through a $\frac{3}{16}$ in. screen. This dust has a higher manurial value in nitrogen, phosphates, and lime than stable manure, and good reports have been received of it from agriculturalists and golf clubs. The second material removed is a fine cinder which passes through a ½ in. mesh, amounting to about 26 per cent. of the refuse. This fine cinder when made into briquettes, with the addition of 8⅓ per cent. of pitch and ½ per cent. of tar, has a high calorific value. The third material is large cinder which, owing to its specific gravity, can be separated by a washing process from the heavier residue and has also a high calorific value. Its fuel value is 11, taking coal as 14, and it is used instead of coal for heating the corporation baths. The large cinder constitutes about 18·5 per cent. of the whole. The heavy material which is separated by the washer amounts to about 14 per cent. and consists of stone, shale, broken pottery, while it also contains a certain amount of unburnt coal which falls out with the heavy debris. The unburnt coal is one of the few useful things not used, but its quantity would not justify the cost of sorting. This heavy residue being washed forms a quite innocuous material for tipping, very different from the stuff at present tipped, being more like clean builders' rubbish. The vegetable matter, amounting to between 3 and 4 per cent., will either be burnt in the destructor or pulverised and added to the dust to increase its manurial value, provided a good market is found for the dust. The "tailings" or larger particles, containing tins (1 per cent.), rags (0·4 per cent.), paper (3·6 per cent.), are carried on to a revolving belt where articles of value are picked off by hand. This hand sorting is light work of a quite unobjectionable nature on sanitary grounds and is necessary because of the varying value of the tailings. For example, during the war a good price could be got for the paper; now there is no market for it. The tins are de-tinned in a furnace and pressed into bales and find a ready market. The oily rags have the oil extracted, the dirty rags are sterilised, and a market is found for the clean remainder and the recovered oil. The total estimated annual expenditure for the new system put before the inspector was £85,000, against which there is an expected revenue from sales amounting to £49,000, leaving a net annual expenditure for the proposed new plant of £36,000. The present annual expenditure in Sheffield on burning and tipping is £50,000, so that the new system is estimated to effect an actual saving of £14,000 per annum. This net expenditure of £36,000 has also to be compared with an estimated annual expenditure of £91,600 if a scheme had been adopted for burning the whole of the refuse of the city at destructors. There was plenty of evidence at the inquiry that the estimated revenue from sales was a very safe one and much below prices which are at present being realised.

If the Ministry's approval is obtained the progress of the scheme will be watched with general interest. Mr. Mortimore (Messrs. Mortimore, Lyon, and Co., Manchester), in his evidence, stated that the analysis of the Sheffield refuse showed it to be similar to that of other towns, and later in the inquiry it was suggested that the dustbins of the country are an untapped source of fuel to the extent of 3,000,000 tons a year. It does not seem likely that the general adoption of gas-fires or central heating will diminish this new source of fuel for years to come, and from the sanitary point of view the new system is eminently desirable. We shall get rid of the nuisances inseparable from tips, and the refuse will be dealt with in a manner which demands a minimum of handling and involves no disagreeable work for those employed in working the system.

BENZYL BENZOATE IN DISEASES OF CHILDREN.

WE have recently[1] called attention to an important new antispasmodic discovered by Dr. David Macht in the pharmacological laboratory of the Johns Hopkins University and to its value in persistent hiccup, whooping-cough, and asthma. Pharmaco-dynamic analysis of the papaverin group of the opium alkaloids, which have a sedative effect on smooth muscle, pointed to the benzyl nucleus as responsible for the sedation. On searching for a simpler compound of benzyl with the sedative effect of papaverin and without its narcotic effect, Dr. Macht found that benzyl benzoate had all the effect of papaverin on smooth muscle and was much less toxic. The field of utility for such a drug, especially in diseases of children, is obviously extensive. Dr. Macht's claims have been confirmed by other observers. In the *American Journal of the Medical Sciences* for January Dr. John Ruhräh has published an important paper on benzyl benzoate in diseases of children. He points out that the drug stops the rhythmic contractions, lowers the tone, and relaxes the spasm of smooth muscle. This action has been observed on the muscle of the intestine, gall-bladder, uterus, and urinary bladder. On the circulation the action is chiefly on the peripheral vessels, producing a fall of blood pressure. But in ordinary cases this action may be disregarded. Dr. Ruhräh has found its action most favourable on general convulsive conditions, though this could scarcely be expected. Thus an infant was circumcised immediately after birth. The wound became infected and 40 to 60 convulsive seizures occurred daily. Four-drop doses of benzyl benzoate, diluted, were given, and later one or two drops at intervals of four hours. The convulsions diminished to half a dozen daily and the child could nurse with comfort and recovered. With regard to whooping-cough, Dr. Ruhräh refers to the notoriously uncertain action of antispasmodics. What quietens one child has little action on another. Belladonna, he finds, gives the best results in the greatest number of cases, but it cannot be left indiscriminately in the hands of the careless. Benzyl benzoate acts fairly well in many cases, lessening the number of attacks, but its action is uncertain. Possibly this may be due to lack of knowledge as to dosage. In bronchial asthma and spasmodic bronchitis he found the effect most happy and more certain than in any other disease. In intestinal colic relief was unusually prompt, and in severe hiccup the results were better than those of any other drug. In pylorospasm (which must be differentiated from cases in which the obstruction is chiefly due to pyloric hypertrophy) atropine proved so satisfactory that other drugs made little appeal. But there are cases in which the amount required to cause relaxation already produced toxic symptoms. In such cases benzyl benzoate is of use. In diarrhœa it may be used to check excessive peristalsis, and, as it does not check secretion, it may eventually replace opium. In spastic constipation it is of value. The drug seems non-toxic, but it is hot and unpleasant to most children, and must be diluted with water, sweetened water, or milk. Older children may take it dissolved in olive oil or in capsules, but plenty of water should be taken at the same time. Ampoules in olive oil for hypodermic use may be had when rapid action is desired. The injection should be intramuscular. Dr. Macht gives the adult dose as 20 minims, but this is too small in many cases. For children the dose may be calculated, according to weight, from the adult dose (taking the maximum, average, and minimum doses as respectively 60, 40, and 20 minims for a patient weighing 150 lb.), or according to age by Young's table.

AN AMERICAN ENDEMIC FOCUS OF LEPROSY.

SOME of the problems associated with leprosy are still unsolved, notwithstanding the advances which have been made in our knowledge of the disease in recent years. Contributions to the literature of the subject are, therefore, specially welcome, particularly when made by earnest and competent observers. In the United States Public Health Reports for Dec. 17th, 1920, two past assistant surgeons of the U.S. Public Health Service, Dr. Mark F. Boyd and Dr. Warren F. Fox, have published a paper entitled "An Epidemiological Study of an Endemic Focus of Leprosy," in which some interesting facts are given respecting the incidence of the disease in a seaport town situated on an island in the Gulf of Mexico, off the coast of Texas, and having a population at present estimated at over 44,000. The name of this seaport is not stated by the authors, but from their description we conclude that the place referred to is the ill-fated port of Galveston. In this area during the past 30 years some 45 cases of leprosy have come under observation, and concerning these various particulars were obtained partly from the patients themselves and partly from local medical practitioners. In addition, 25 other cases were heard of, making a total of 70 in all, but of the latter group little definite information was available, consequently the authors have confined their special inquiries to the first-mentioned 45 cases. Of these 26 are still alive, 13 have died, and the remaining 6, although presumably still living, have left the town and taken up residence elsewhere. Five of the 45 cases were considered to be imported instances, 36 were regarded as having contracted the infection locally, and in the remaining 4 the origin of the disease was too obscure to allow of any statement being made. Omitting the imported cases, of the remaining 40, 7 were negroes, 29 were whites, and the racial origin of 9 was not ascertained. The incidence of leprosy among negroes and whites appeared to be only in proportion to the distribution of the population, but cases were more numerous among whites of foreign-born parentage than among native-born whites. This incidence seemed to be proportionately higher among those of German parentage than among those of other descent. The significance of this is not clear, but it is suggested that it may possibly indicate a greater susceptibility among persons of German ancestry, or perhaps that the strain of leprosy infection prevalent in the affected area may be of Teutonic origin. As regards sex, 25 of the 40 cases were males and 15 females. With respect to age-distribution, more cases developed their illness between 10 and 20 years than in any other period, though no age-group appeared to be immune. Length of residence in the area seemed to be a more important factor than age in determining the onset of the disease. Most of the leprous patients developed their illness after ten or more years' residence in the town. The bulk of those who suffered were poor persons of the labouring class. Single cases occurred in 19 houses; two houses had each two cases, and in one house there were three cases. The tubercular type was more common than the anæsthetic, the mixed type being more frequent than either of the others. The majority of the patients gave a history of contact or association with a previous case before the development of their own attack.

---

[1] THE LANCET, 1920, ii., pp. 512, 515, 838.

As a result of their investigations the authors formed the opinion that there existed in the town a number of unrecognised lepers. The incidence of the malady in this area is therefore probably greater than the previous figures would lead us to suppose; in any case, it appears to be higher than in any other of the recognised endemic foci of leprosy in the United States. In the annual report of the Surgeon-General of the U.S. Public Health Service for 1918 it is stated that the number of cases of leprosy in the whole of the United States in that year was 209. The spread of leprosy in this Texan seaport town is apparently due, to a great extent, to contact with recognised or unrecognised cases of the disease. Various other hypothetical modes of spread were considered, and as regards possible transmission of the infection to man by rats or by insects no satisfactory evidence was forthcoming. The relation of a fish diet to the incidence of the disease was also examined, but this was also dismissed as being unsupported by any evidence. In concluding their contribution the authors draw attention to the fact that "absolutely no official control or supervision in any form has ever been exercised over the leprosy cases" in this affected area. It is proper to mention that these studies of leprosy in the seaport town in question were undertaken by Dr. Boyd and Dr. Fox in an unofficial capacity.

THE SUPRARENAL GLANDS IN DEFICIENCY DISEASES.

THE widespread effects of the absence of vitamines in the diet on certain organs apparently remote from their influence is perhaps only just becoming recognised. R. McCarrison, in his observations[1] on the genesis of œdema in beri-beri states that in pigeons suffering from experimental beri-beri the œdema is always associated with considerable increase in the size of the suprarenal bodies and that four-fifths of the animals with enlarged suprarenals show some form of œdema. The adrenalin content was increased proportionately to the weight of the organs. The pigeons had been fed on polished rice heated in an autoclave, until they showed signs of polyneuritis. In 10 out of 22 pigeons œdema occurred. The increase in size of the suprarenals is a true hypertrophy at least of the medulla, and if the increase of the adrenalin content can really be brought into causal relation with the œdema it is possible that this factor may be found to play some part in the production of œdema generally. While the size of the suprarenals appears to have relation to the absence of the antineuritic factor, it would appear that the suprarenals are also affected by diets deficient in the antiscorbutic vitamine, as shown by the experiments of Victor K. La Mer and H. L. Campbell, of Columbia University. These observers fed young guinea-pigs, weighing 250-300 g., on a diet deficient in the antiscorbutic vitamine, and found an increase of weight of the adrenal glands amounting to approximately 100 per cent. when computed on the basis of body weight minus alimentary canal. Control animals which have been subjected to starvation do not show an increase of adrenal weight, which in those fed on scorbutic diet is directly proportional to the time during which their food has been deficient. It is most pronounced in those animals whose life has been prolonged by the partial protection afforded by small but insufficient quantities of tomato juice. La Mer and Campbell interpret the increased weight as indicating a compensatory response to the decreased adrenalin production known to exist in the scorbutic animal, a point which has interest in connexion with the extensive intramuscular and intestinal hæmorrhages found in scurvy. The heart and kidneys are increased on the scorbutic diet, while there is no evidence that the liver is affected by a lack of water-soluble C alone.

TESTING OF CLINICAL THERMOMETERS.

AN announcement was published last week by the Board of Trade that there is reason to believe that numbers of imported thermometers are being offered for sale in this country without having been officially tested. The reminder is therefore timely that, under the provisions of the Clinical Thermometers Order, 1918, no person may sell, offer for sale, supply, or deliver any clinical thermometers which have not been tested, approved, and marked at the National Physical Laboratory. Purchasers should, in their own interests, see that any thermometers offered to them bear the official test mark—namely, a monogram formed with the capital letters N.P.L., followed by two figures denoting the year of test. The requirements apply to foreign thermometers imported into this country equally with those of British manufacture, although clinical thermometers exported from the United Kingdom need not at present be tested and marked.

A BICAMERAL HEART.

LAST November a curious specimen of cardiac abnormality was brought before the Section of Medicine of the Royal Society of Medicine by Professor A. Keith and Dr. J. J. MacDonnell, and an illustrated and detailed description of it appears in the current issue of the Society's Proceedings. As Professor Keith remarks, in his report on the specimen, every one of the abnormalities shown has been frequently seen before, but the peculiar combination appears to be unknown. The case was one of complete transposition of viscera, and the apex of the heart was in the right nipple line, but the autopsy disclosed a strange state of affairs. Briefly, there was an apparently ordinary aortic arch, directed to the left, but attached to the heart in front of a dilated vessel, which otherwise was in the place of a normal pulmonary artery. The normally situated ductus arteriosus was patent, and through it the systemic blood passed, for the aortic arch received no blood from its ventricle. This dummy aorta arose from a ventricle which was the ordinary right ventricle, morphologically and descriptively, while the "pulmonary aorta" came from a ventricle to the left and in front of the other. Thus, the ventricles were not transposed, while the aortic stems were transposed so far as their ventricular relations went. The relations between the big vessels are those which would come into being as a result of a reversal of the direction of the line of septum formation in the single aortic stem, in keeping with the general transposition, but not with the left-sided arch. The ventricular position is normal, and it may be pointed out that the heart sometimes does not share in situs inversus. The intra-ventricular conditions indicated that the embryonic development of the ventricular and bulbous regions had been more or less normal, so that the inversion of the aortic septum is all that need be postulated here. But at the auricular end of the heart the auricle on the left side received the two venæ cavæ as well as the pulmonary veins, and there was no inter-auricular foramen, so that the auricle to the right received no blood and could not feed the right ventricle and aortic arch. The pulmonary veins joined into a common trunk—a primitive embryonic stage—and opened into the auricle through what was really a greatly distended sinus venosus or coronary sinus; an additional upper pulmonary vein on the right side, however, opened into the right innominate vein. This, as Professor Keith points out, is doubtless the remnant of a drainage into an embryonic vena cava on that side. Possibly this last vein represents an opening into the azygos system and thence into the vena cava, and might be looked on as a modified bronchial vein. The other pulmonary veins are apparently in a persistent embryonic stage, but the rest of the arrangements in this curious auricular region would seem to defy probable analysis from a developmental point of view; it is another example of the inadequacy of normal embryology to account for abnormalities under certain conditions, in which we get occasional glimpses of deeper causative genetic factors of which we know nothing. The specimen is a most interesting one as a pathological condition, and it is only necessary to add that it was consistent with a measure of independent life, as the child lived seven months, dying apparently from capillary bronchitis.

HEREDITARY HÆMORRHAGIC TELANGIECTASIA.

IN a review of the literature of hereditary hæmorrhagic telangiectasia associated with familial epistaxis, Dr. Hyman I. Goldstein,[1] of Camden, N.J., who himself reports 11 cases in one family, states that 31 families affected with this disease are on record, as well as several cases which are not altogether typical. Isolated examples of the condition with no other instances occurring in the patients' families have been described. In some cases hereditary telangiectases have been noted in one or several members of a family, but without recurring epistaxis; in others there were persistent recurrent attacks of epistaxis of the familial type, but without telangiectases either in the patient or other members of the family. Males and females are affected alike, and are equally capable of transmitting the disease to their offspring. Hæmorrhage is the one constant symptom. In the great majority of cases it occurs in the form of epistaxis, but in some cases hæmorrhage may occur from the telangiectases on the tongue, lips, fingers, buccal mucous membrane, or even from the rectum. Multiple telangiectases, which constitute the sole characteristic of this condition, are found most commonly on the buccal and nasal mucous membranes and upon the lips. They may also occur on the face, feet, hands, ears, scalp, neck, forearms, and chest. The telangiectases associated with epistaxis may occur in three forms: (1) pin-point; (2) spider form, the most common; and (3) nodular. The lesions are apt to become prominent and increase in numbers between the ages of 35 and 50. Many of the patients present symptoms of profound secondary anæmia. The diagnosis is not difficult. The cases must not be confounded with hæmophilia, hæmorrhagic diathesis, purpura, scurvy, pernicious anæmia, or "the phthisical state with hæmorrhages." The clotting and bleeding time is always normal, and there is no history of hæmophilia. The blood platelets are not appreciably reduced, and the resistance of the red cells remains normal. No general treatment seems to be effective, but local treatment may reduce the number and severity of the hæmorrhages and improve the patient's general condition.

COMPARATIVE RESISTANCE OF TISSUES TO LOCAL ANÆMIA.

AMONGST the many experiments which were made in the attempts to allocate the relative share of blood pressure, blood flow, and the renal tubules in the secretion of urine was the experimental ligature of the renal vein. It was found that its closure for even a very short time led to prolonged cessation of the secretion, and that when this was resumed the urine contained albumin. Loren R. Chandler, of Stanford, California, has now studied the effects of producing a temporary renal anæmia of two hours' duration by placing a ligature about the renal artery of a rabbit. The rabbit is killed from one to four days later, when histological study invariably shows necrosis of practi- the entire cortical tubular epithelium, with few, if any, changes in the glomerular and interstitial elements. This method of producing epithelial necrosis with the minimum amount of injury to other elements adds another method for the study of epithelial regeneration and the pathology of renal secretion. It has been applied also to the study of hepatic function and regeneration, and tests have been made of the effects of temporary local anæmia of the liver of dogs. To produce this anæmia Eck's fistulæ were made. Five to seven weeks later the abdomen of each dog was reopened, and temporary ligatures placed about the hepatic artery and portal vein, and the ligatures kept in place from three to 12 hours. The animals were killed two to six days later. During the period of ligation the dogs showed no toxic symptoms. After removal of the ligature they appeared in every way normal until they were killed. At the autopsy the histological examination showed that in those with vessels ligatured for three hours there was no thrombosis, no necrosis or atrophy of the hepatic parenchyma; a moderate degree of fatty degeneration was mainly confined to the central third of the lobule. In the animals subjected to 12 hours of local anæmia there was similarly no thrombosis or necrosis; there was marked fatty degeneration of the central half of the lobule, with slight atrophy of the parenchyma immediately surrounding the central vein. It would appear that the power of the hepatic cells to resist local anæmia is in striking contrast to the sensibility of the secreting renal epithelium. In fact, the infrequency of infarcts in the liver, usually attributed solely to the pressure of the double hepatic circulation, is probably due in large measure to this power. It affords yet another example of the wonderful stability of the liver cells, which, though apparently so simple in structure, are yet so manifold in their functions.

THE PERSONAL ELEMENT IN EFFICIENCY.

AN Efficiency Exhibition promoted by the proprietors of the *Daily Mail* is being held this week at Olympia, West Kensington, and is to remain open until Feb. 26th. The promoters have shown through their selection and arrangement of the exhibits how interest is growing in the human side of efficiency, in contrast with the technical or mechanical side. The exhibits of two hospitals, St. Mary's and the Middlesex, imply a recognition that efficiency depends upon health, and health in its turn upon medical knowledge. A good idea is given to the public how chemical, physiological, and bacteriological research is carried out; the Middlesex stall is particularly well equipped, and is attracting much attention. In another place the People's League of Health are showing how inefficient in matters of health the nation is to-day, emphasising the need for further research and the necessity for popularising knowledge. In the gallery Major Frank Gilbreth, from America, who is himself in attendance at the exhibition, has a display of unusual interest, setting forth his methods of adding to efficiency by minimising industrial fatigue through scientific motion and time study. The whole of the annexe, placed at the disposal of the Ministry of Labour, is devoted to disabled ex-Service men who have been trained to become efficient craftsmen, and there they may be seen weaving, cabinet-making, printing, laying bricks, and doing a number of other things—a wonderful demonstration of what determined men can do to overcome physical disabilities. The need for the personal and human note, for physiological and psychological health, in order to ensure efficiency, was borne testimony to by both Sir Robert Horne and Dr. Macnamara in their speeches on the opening day. The same factor appeared in planning the scientific conferences which are taking place daily; for the pride of place was given to health questions, covering such diverse subjects as maternity, child welfare, food, milk-supply, industrial hygiene, tuberculosis, and other matters, each discussed by experts. Lady Barrett and Professor W. M. Bayliss presided on Feb. 10th, when Dr. C. W. Saleeby and Professor E. L. Collis spoke. Sir H. Baldwin, Mr. E. B. Turner, and Dr. A. Latham were among the speakers on the following day. Dr. H. M. Vernon and Professor A. F. Stanley Kent contributed to the conference on fatigue elimination. Dr. S. Russell Wells presided at a discussion on commercial education. We welcome this new note in the community, and consider that should the Efficiency Exhibition do nothing else it will have rendered good service by bringing personal efficiency so prominently before a large public.

TORSION OF THE FALLOPIAN TUBE.

Dr. S. D. Dearborn has reported[1] a case of a very rare condition—torsion of the Fallopian tube. The patient was a married nullipara, aged 50 years. She was vigorous and active. At intervals of a few weeks or months she suffered from pains in the lumbar region and pelvis on both sides, which lasted for a short time, with complete freedom in the intervals. The catamenia occurred every three and a half to four weeks. Five years ago they had been excessive, but of late years they had been normal. After working in the garden she was seized with severe pain in the right loin. Examination showed marked tenderness in the region of the right kidney, the lower portion of which was palpable and freely movable. The pulse, temperature, and urine were normal. On the following day the pain was in the region of McBurney's point, where there was also tenderness. Vaginal examination showed an apparently normal uterus and slight feeling of resistance in both fornices. On the third day the pain occurred at intervals, but was more severe over the whole lower abdomen. There was tenderness over Morris's and McBurney's points. Increased resistance to abdominal palpation, but no absolute rigidity of the recti, and moderate distension were found. The nurse reported a "show" of blood from the vagina on the previous night. Vaginal examination revealed a tender mass behind the cervix. Examination was not very satisfactory because of a fat abdominal wall, distension, and general tenderness. The pulse was 90 and the temperature 100·6° F. The bowels had moved freely and there was no nausea or vomiting. The diagnosis was probably appendicitis with salpingitis and less probably extra-uterine pregnancy. On operation the right tube was found to be of twice its normal size, twisted once and a half on itself, and black as gangrenous intestine. The fimbriated end lay behind the uterus just above the junction with the cervix. The right ovary was of the size of a plum and somewhat darker than normal and it contained several small cysts. The left tube was enlarged to thrice its normal size, slightly injected, and filled with pale, straw-coloured fluid. The appendix was enlarged, convoluted, and deeply injected, and it contained a concretion at its tip. The tubes, ovaries, and appendix were removed. Convalescence was uneventful.

A NEW ANTI-SERUM FOR TUBERCULOSIS.

THE first communication on Mons. Henri Spahlinger's serum treatment for tuberculosis was made to the Académie de Médecine shortly before the outbreak of war by Professor Letulle on behalf of the discoverer. Mons. Spahlinger is a Swiss bacteriologist who has spent several years in a painstaking endeavour to unravel a very knotty problem—viz., the use of antiserums in the treatment of tuberculosis. The report made six years ago was preliminary to more extensive study and contained records of a small number of selected cases treated by a few physicians in London and Paris. A *further communication* has now been given to the medical public in a report made to the Académie des Sciences, on behalf of Mons. Spahlinger, by Professor D'Arsonval. This report has already attracted the attention of the daily press both in Paris and in London. It contained two sets of recorded cases by British physicians, Dr. A. H. Croucher and Dr. Leonard Williams. The former states that the patients treated by him with Spahlinger's method in 1913 are still alive and well, including two cases of laryngeal tuberculosis. All were cases of advanced pulmonary lesions at the time of treatment, and they are now all at work with their disease apparently quiescent. Dr. Williams gives an account of a series of cases of surgical tuberculosis and of open pulmonary tuberculosis with bacilli in the sputum and physical signs of advanced disease. He reports that when examined in October, 1920, these cases were found to be free from active tuberculosis, and that the condition of the lungs in the pulmonary cases was remarkably good. No bacteriological details are given in the report, but we note that Professor D'Arsonval's communication states that the treatment is based on the progressive destruction of tubercle toxins and subsequent active immunisation. According to this communication Mons. Spahlinger divides his cases into two classes: (1) acute cases treated by means of "complex antitoxic and bacteriolytic" serums; and (2) chronic cases treated by vaccination with a series of antigens and ferments, the former being derived from the bacillary substance of the tubercle bacilli. Patients are finally treated with a graduated series of injections of these different antigens given separately. It is impossible to make fair or useful comment on Mons. Spahlinger's work at its present stage. We must await further enlightenment in regard to those laboratory data without which an immunological remedy cannot be claimed as specific.

A FAVOURED UNIVERSITY.

SHORTLY before the war Mr. G. A. Wills and Mr. H. H. Wills decided to build for the University of Bristol a block of new buildings, to include libraries, an assembly hall, and a tower, in memory of their father, Mr. Henry Overton Wills. The war not only delayed the accomplishment of this purpose, but it also greatly increased the cost. Last week we chronicled the intention of the donors to add a sum of £200,000 to their former benefaction in order to complete the buildings, which are already making good progress. From the same source the University will also receive money for the building and equipment of a new physics department, as well as a public hall to be used as a students' union and various hostels and halls of residence for students. In the near future the University of Bristol will find itself possessed of a fine set of buildings, largely through the repeated generosity of one family. The sensational Rockefeller benefaction to University College Hospital and Medical School led to some criticism of the meagre support given for educational and *research purposes by wealthy men in this country*. Bristol is exceptionally happy in having stimulated the local patriotism of citizens who, having once decided to support the University, keep watch over its changing needs and supplement with such a lavish hand their previous benefactions.

ALBUMINURIA AND EOSINOPHILIA IN SCABIES.

Dr. Joseph M. Hayman, jun., and Dr. Temple S. Fay,[1] of Philadelphia, have made a study of the frequency of albuminuria and eosinophilia in scabies. Albuminuria was found in 10, or 20·4 per cent., of 49 scabies patients examined. In these 10 cases the eruption was generalised, and none showed any peculiar type of lesion, nor was pustulation especially in evidence. In all but one case, in which there was a light cloud, the albuminuria was slight and transient. Hyaline casts were occasionally present in one case, but in none were the urinary findings of any clinical significance. As regards the cause of the albuminuria, the writers exclude secondary pyogenic infection as a factor, for albuminuria occurred independently of pustulation in 100 per cent. of these cases. Treatment was undoubtedly reponsible for the phenomenon in some cases, as was shown by the higher incidence of albuminuria in treated cases (23 as compared with 17 per cent.). The frequency of albuminuria was too high to justify the supposition that it was always the manifestation of pre-existing nephritis, and it was also too transient to indicate a genuine nephritis. Like Nicholas and Jambon, Dr. Hayman and Dr. Fay regard the albuminuria as a manifestation of the cutaneous disease itself, but reject three of the factors incriminated by the French writers—viz., suppression of the skin function, toxin of the parasites, and absorption of products from detached cells in the cutaneous lesions. The most probable explanation seems to be a renal hyperæmia caused by irritation of peripheral nerves at the skin lesion similar to what occurs in various vaso-motor disorders such as Raynaud's disease, angio-neurotic œdema, and occasionally pemphigus. In 55 scabies patients the blood was examined by the writers for eosinophilia, with the result that 32 patients, or 58 per cent., showed 5 per cent. of eosinophils or more, and 20 of these, or 36·6 per cent. of the series, showed 7 per cent. of eosinophils or more. The degree of eosinophilia was, in general, proportional to the extent of the infestation, the higher percentages being found in the more extensive attacks, and the low or normal counts in cases where the lesions were very recent or slight. There was no increase of blood eosinophilia in the neighbourhood of the cutaneous lesions. As it is so variable in itself and so common in other skin conditions, the writers do not regard eosinophilia as of any value in the differential diagnosis of scabies.

SIR WILLIAM RICHMOND.

THE death, after protracted illness, of Sir William Blake Richmond must not pass unnoticed in these columns, for his interest in and admiration of scientific medicine was unbounded, and he was a first-class topographical anatomist, as well as a man of all-round accomplishment. As a painter he excelled both in portraiture and imaginative landscape; he was a bold and original sculptor; and his scheme of decoration for St. Paul's Cathedral, though much criticised, remains in the opinion of all a wonderful piece of work. But it is as a sanitary reformer that he should be gratefully remembered by medical men. No doubt the destructive influence of coal-smoke upon pictures, sculpture, and decorative façades made him its declared enemy, and when the Coal-Smoke Abatement Society was started it was natural to find Sir William Richmond its President, with Mr. O. B. Thomas as secretary, and Dr. Harold Des Vœux as treasurer. Art and medicine here joined hands in a piece of constructive hygiene for the benefit of posterity, and the town-dweller will gain immensely in the future as the ideals of the society obtain realisation.

Miss Anne Louise McIlroy, M.D., D.Sc. Glasg., has been appointed to the University Chair of Obstetrics and Gynæcology, tenable at the London School of Medicine for Women. Dr. McIlroy will direct the Obstetrical and Gynæcological Unit at the Royal Free Hospital.

THE summer meeting of the Section of Laryngology of the Royal Society of Medicine will be held on June 2nd and 3rd, when a dinner in connexion with the meeting will be held. The agenda will include papers and demonstrations, an exhibition of instruments, and a museum.

UNDER the auspices of the Fellowship of Medicine Dr. Gustave Monod, of Vichy, will deliver a lecture at the Royal Society of Medicine, 1, Wimpole-street, London, W., on Wednesday, Feb. 23rd, at 5 P.M. The lecture will be illustrated by a retarded kinema, and will be a study of athletic movements, cardio-pulmonary circulation, and an analysis of golf shots by this means. Dr. Monod, who is paying a visit to this country in the interests of the Association pour le Développement des Relations Médicales of the Paris Faculté de Médecine, will also speak on the closer relations between French and British medicine. Members of the profession and friends are invited to be present.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

THE HUNTERIAN ORATION: ADMISSION OF H.R.H. THE PRINCE OF WALES TO THE FELLOWSHIP.

ON Monday last the Hunterian Oration of the Royal College of Surgeons of England was delivered in the afternoon at the College by Sir Charters J. Symonds, the Orator of the year (see p. 359). Sir Charters Symonds, using the career of Sir Astley Cooper for the purpose, illustrated the influence which Hunter had upon medical progress and medical education, acting through a group of his enthusiastic and distinguished pupils. He further made an eloquent plea for the simplification of the medical curriculum, urging that more stress should be laid on the clinical side.

The Hunterian Festival Dinner.

The Hunterian Festival Dinner was held in the library of the College the same evening, Sir ANTHONY BOWLBY, the President of the College, presiding, His Royal Highness the Prince of Wales being present and a large group of distinguished guests. After the loyal toasts the PRESIDENT proposed the health of the Prince of Wales in the following terms:—

May it please your Royal Highness: The Royal College of Surgeons of England is the descendant of two civic institutions which date back to the fourteenth century—namely, the Guild of Surgeons and the Company of Barber Surgeons—but it was founded by Charter as a Royal College in the year 1800. It was not, however, until the College celebrated its centenary in the year 1900 that it became empowered to create Honorary Fellows, and its first Honorary Fellow, Sir, was your illustrious grandfather, King Edward VII., who, while Prince of Wales, was graciously pleased to accept our diploma in June, 1900. At a later date His Majesty King George bestowed upon us a similar distinction, and I have now the honour of welcoming your Royal Highness as the third Prince of Wales to become an Honorary Fellow of the College.

Since the election of its first Honorary Fellow the College has from time to time elected other Fellows, and has generally done so in order to commemorate some important event. Following this precedent, it proceeded on July 24th, 1919, to commemorate the close of the Great War by electing six honorary Fellows from those who had specially distinguished themselves in the war, and it was under these circumstances, Sir, that we requested you to allow us to propose your name. We know the encouragement that your presence has been at the Front; we appreciated your zeal and keenness for everything that benefited our soldiers; and, above all, we admired the spirit in which you performed the duties allotted to you as an officer in His Majesty's army.

On the same date we elected His Royal Highness, the Duke of Connaught, not only as a representative of the Royal House who had been closely associated with the army all his life, but also because he was the Colonel-in-Chief of that Royal Army Medical Corps, which had served with such great distinction, and won for itself such universal praise. We elected Dr. Pierre Duval, the distinguished French surgeon, and Dr. Depage, the equally eminent Belgian professor, both of whom had so closely coöperated with us in the field and had personally attended many British soldiers.

Finally, we elected two representatives of our sister nation, the United States of America, and we chose Brigadier-General Finney, the "chief surgeon" to the American army in France and the professor of surgery at Baltimore, and Charles Mayo of Rochester, who had acted as adviser to the Army Medical Service in America, and whose fame is world-wide. The medical professions of Great Britain and of the United States have for many years enjoyed the closest coöperation and friendship, and we were in no way surprised that, as soon as ever the drums of war beat to arms, the surgeons of America sprang to our aid. Within a very few months they supplied the personnel of six general hospitals and, at a later period, over one thousand of them served in our army in France pending the arrival of their own troops. They served in our base hospitals, in our regiments, our field ambulances, and our casualty clearing stations during the third battle of Ypres, and amongst them we were especially glad to welcome some of our own Honorary Fellows.

Such, Sir, is a brief record of the claims of the Honorary Fellows elected as representatives of our Allies at the time when you consented to accept our Diploma, and the College has never been more fortunate than in the distinguished names which it has been able to add to its roll at the end of the Great War. The Royal College of Surgeons performs various public duties which I will not detail. It is the national custodian of the unequalled Hunterian Museum. It possesses a most valuable library open to the whole medical profession; and the Members and Fellows who have passed its examinations number, at the present time, nearly 18,000. Our great master, John Hunter, was the Surgeon-General *to the army for some years before his death in* 1793, and ever since his time large numbers of men holding our diplomas have served with the Imperial Forces of the Crown. The present Chief Medical Officers of the Navy, of the Army, and of the Air Force, are all Members of our College, and several thousand of our Fellows and Members served in the late war. Over 350 of these gave their lives for their country, and your Royal Highness knows from your own experience in France that these lives were not given in vain.

We, *Sir, in common with all sections of the community,* have watched with the deepest interest both the career of your Royal Highness in the war, and also your more recent and invaluable missions to those great British possessions overseas which have so gallantly supported our common cause. We recognise that, both in war and in peace, in France and in the Dominions, you have been a fertile source of inspiration and of good fellowship, and, at the same time, we like to recall that, however far you may have roamed, you have not visited a dominion or a *colony in which our College was not represented. We may,* indeed, justly claim that, while the heart of our College is in England, our Fellows and Members circulate throughout the world. You, Sir, have been frequently described as "Britain's best Ambassador," but, if I may say so, you are far more than that. An Ambassador is but the delegate of a friendly country to a foreign nation, while you are a living and indispensable link in that human chain of common aspirations, common ideals, and common patriotism which binds together all parts of our great Empire in a bond which is infinitely *more enduring and* unbreakable than all the Treaties that ever have been or ever will be written.

We use no mere form of words when we say that we fervently trust you may long live in health and happiness to further the good work for the Empire you have so successfully begun. In the name of the Royal College of Surgeons of England, Sir, I beg to thank you most heartily for coming amongst us this evening, and for doing us the honour of becoming an Honorary Fellow.

H.R.H. the PRINCE OF WALES then signed the roll of the Fellows of the College and returned thanks to the President and Council for his election in sequence to the election of his grandfather and father, mentioning also that he was proud to receive the diploma at the same time as the Duke of Connaught and the eminent group of surgeons from Allied countries. He admitted that before the war neither he nor any of his contemporaries had much idea what the letters F.R.C.S. meant, but the war brought home to them, and indeed to everybody, the full significance of the initials, as representing the long years of progressive research and experiment of surgery.

"Before we went out to the front," he said, "speaking for myself and my contemporaries, we began for the first time to take a practical interest in surgery. The doctors of our units lectured to us and our female relatives and friends practised on us, while later, those who got in the way of a Hun bullet or shell became passive subjects for surgical work. All who served in the Great War had great or small dealings with your profession and its members, and I have never heard anything but the deepest gratitude for the medical branches of both Services and those who belong to them, from the surgeons—those who had regular commissions, and thousands of them, many members of this College, who joined up—down to the sick-bay stewards, and, in the case of the army, the orderlies. I include here those eminent surgeons who, like our chairman, gave their valuable time and their help and their advice. Among the most gallant episodes *of the war are those of battalion medical* officers in the army and their small staffs of stretcher-bearers. The work done by our surgeons and by our doctors is one of the finest chapters in the history of the war, and there is no doubt that the fact that the men knew that if they were wounded they were going to be well treated cheered them up more than one can understand.

It is in this building that we are sitting in to-night that so much of the work and the knowledge which made all this possible had its origin. Knowing what that work was, having seen something of it for myself, and realising what is being done here now, makes me doubly proud of the honour which has been done me to-night by having been admitted to your Fellowship. Thank you very much."

The toast of the memory of John Hunter having been drunk in silence, Sir CHARLES BALLANCE, Senior Vice-President of the College, proposed the health of the visitors in a speech in which he vaunted eloquently the beauty of surgical work, its indispensability, and the inexpressible satisfaction given by its happy accomplishment. He mentions as particular examples of surgical progress the successful *experiments upon the* transplantation of organs, and the rejuvenescence of aged hairless rats by a slight operation. He alluded humorously to the vista which such procedures opened up.

The toast was replied to by the SPEAKER of the House of Commons, who said there were three professions—surgery, law, and politics—to the last two of which he himself belonged—which were absolutely indispensable. *No one went through life without consulting the doctor* or the lawyer, or cursing the politician. They had, he said to a highly amused audience, a collection of rats in his own Chamber, and some of them were hairless, but there was no great desire to see them rejuvenated, while he indicated that rejuvenescence had one drawback, it was likely to stop promotion. He bore testimony to the good work done by members of the medical profession in Parliament.

Sir GEORGE PARKIN proposed the health of the Hunterian Orator, congratulating his fellow Canadian, Sir Charters Symonds, whose admirable work in the war was known to everyone present, on reaching the great distinction in his profession implied by his selection to deliver the Hunterian Oration. He pointed out that, whereas up to quite recent times the colonies and distant possessions had drawn from the mother country their distinguished leaders, now a reflux had commenced, and we were witnessing the mother country receiving gladly the services of the children from her outlying provinces. This interchange of work and personnel between all parts of the empire he happily compared with the discovery by Harvey of the circulation of the blood.

Sir CHARTERS SYMONDS, having briefly responded, a very successful dinner came to a close.

ROUMANIA.

(FROM OUR OWN CORRESPONDENT.)

The Health of the City of Budapest.

THE Statistical Bureau of the city of Budapest has just issued its report for the year 1920. Every year some new feature is introduced, and in this issue a summary of the statistics appears on the first page, giving at a glance the condition of public health during the past year. The population of the city is nearly 1,000,000, the average density of distribution 34·06 per acre. The birth-rate was 19·1 and the death-rate 15·06. Of the total deaths about 1 in every 4 (125 per 1000 births) was under 1 year. The zymotic death-rate was 2·28 per 1000. The birth-rate has been steadily falling since 1914, *when it was 29·44 per 1000, and is at present* lower than in any other capital of Europe, except Vienna. To compensate for this the low annual death-rate constitutes a record in the annals of the city. Ten or fifteen years ago 18–19 per 1000 was a good average, and in the "sixties" and "seventies" such figures as 23 or 27 per 1000 were common. The age-distribution of deaths was much the same as in former years; the city has been comparatively free from serious zymotic diseases, but whooping-cough and *diphtheria* have been somewhat more prevalent. Three cases of hydrophobia, following rabid dog bites, occurred. Deaths from tubercle show a slight but definite decline; deaths from cancer remain fairly stationary.

The number of notified infectious diseases totalled 5219 cases, showing a slight decrease from the preceding year. Scarlet fever was much less, but diphtheria was more prevalent. No small-pox case occurred at all. Only one outbreak of typhus occurred, being limited to one street. Typhoid was twice as frequent on the right bank of the Danube in Buda, which lies much lower than Pest; diphtheria was very much more prevalent in Pest and its suburbs. The increase of diphtheria is the chief fact the sanitary authorities have to face. The cause of this is not apparent. It is not connected with milk-supply or obvious sanitary defects, and is most common in the best parts of the city.

A Disputed Fee.

An eminent Roumanian surgeon, recently summoned to a member of the English Mission, performed upon the latter an operation for incarcerated hernia. The fee asked by the doctor was 10,000 lei, the charge including cost of 14 days' residence in a sanatorium. The Englishman considered the fee excessive, and offered 5000 lei. This the doctor refused, and instituted legal proceedings in order to recover the amount claimed. The case went against the surgeon, who then gave notice of appeal; the Court of Appeal has now confirmed the decision. The surgeon was allowed 5000 lei, and had to pay the costs of both actions, amounting to about 1200 lei.

An Incorrect Diagnosis.

A case of considerable importance to the medical profession has recently been tried at the Bucharest Court. It appears that the porter of a hotel was attended for a skin disease by a medical man, who made a diagnosis of syphilis. The patient's wife thereupon left him, and the secretary of the hotel discharged him. The patient was then informed by a club doctor that his malady was not syphilis, but simply scabies. The man sued his own medical attendant for damages, but did not claim his wife. The nature of the disease does not appear to have been disputed at the trial. The main point at issue was that of negligence. The judge held that the plaintiff's discharge was the direct consequence of the error, and awarded him a sum equivalent to six weeks' salary, and costs.

Sleeping Palsy in Roumania.

Two cases of encephalitis lethargica recently occurred in an infantry regiment stationed at Craiova. Up to the present the source of infection has not been detected, although Professor Langier, chief medical superintendent of the town, has made careful investigations. Extensive preventive measures have also been instituted.

Hiccup Epidemic in Budapest.

The present epidemic of hiccup is the second which has occurred in Budapest; the affection is apparently of a less serious type than previously, although serious cases were observed, and one case ended fatally with symptoms of syncope. Nervously disposed subjects are chiefly affected, and suggestive therapy is of great value. In a case of Dr. Balint, lecturer on Internal Medicine at the University of Budapest, the hiccup ceased instantly when he shouted to the patient: "Leave off that hiccup, otherwise you will die!" In other cases light faradisation stopped the attack. Where treatment is of no avail the hiccup ceases naturally after four or five days.

Jan. 24th.

BRIGHTON AND HOVE DISPENSARY.—In acknowledgment of his services in organising an Oriental bazaar, which realised £1035, in aid of Hove Hospital, the Hove branch of the Brighton and Hove Dispensary has made the Mayor and Mayoress of Hove (Councillor and Mrs. F. W. A. Cushman) honorary life governors.

LITERARY INTELLIGENCE.—Messrs. J. and A. Churchill announce the early appearance of "Critical Microscopy: How to get the best out of the Microscope," by Dr. A. C. Coles; "Ammonia and the Nitrites," by Dr. E. B. Maxted; and an eighth edition of Mr. Bolles Lee's "Microtomist's Vade-Mecum," under the editorship of Dr. J. Bronte Gatenby. For this edition Professor W. M. Bayliss has written a new chapter on the Theory of Dyes and Staining; Dr. Da Fano has recast the chapters on Neurological Methods, and Dr. A. Drew has written a new section on Protozoological Techniques; the chapter on Bone and Teeth has been revised by Dr. J. Thornton Carter; Dr. W. Cramer and Dr. Gatenby have written a special section dealing with the study of Fatty Substances.—Messrs. Kegan Paul, Trench, Trübner, and Co., Ltd., will publish at an early date a translation of "Das Liebe Ich" ("The Ego"), by Dr. Wilhelm Stekel.

Public Health.

SCHOOL MEDICAL SERVICE:

REPORTS OF SCHOOL MEDICAL OFFICERS.

Derbyshire.

THE total number of children enrolled as attending the 168 council and 212 voluntary schools under the Derbyshire Education Committee in 1919 was 76,527; of these 24,791 were systematically examined in the code groups, and in addition 2083 were dealt with as special cases. In the former category 4026 were found to be in need of medical treatment (16·24 per cent.), while an additional 39·68 per cent. were recommended to be kept under observation. The defects most prevalent were, as usual, those of the throat and eyes. Enlarged tonsils, or adenoids, or both, were found in 4780 children, treatment being considered necessary in 1505 cases. The eyesight was sufficiently defective to need treatment in 1638 children, and in addition 1981 required to be kept under observation. Organic heart disease was diagnosed in 190 children, of whom 48 were referred for treatment. The remaining 142 cases "require to be kept under observation," but apparently no medical treatment is considered to be necessary or desirable, although they are classified as "organic." No particulars are given as to the nature or degree of organic heart disease that is considered not to require medical care, the responsibility for the health of these children in school being left to the respective teachers concerned, who (it is to be presumed) have been warned. Mention is made of the connexion between heart disease and the presence of adenoids, and it is recommended that such cases should be watched and not allowed to remain in school in damp clothing. Dr. J. Perrin Brown, reporting on the work at the Tonsil and Adenoid Clinics, emphasises the fact that this is not merely concerned with affections of the nose and throat, but that "its chief value is that we are dealing with the Beginnings of Disease; 30 per cent. of the tonsils recently enucleated have been found to contain tubercle bacilli. This is essentially preventive treatment; we have caught the tubercle bacillus at its port of entry. Had it been left the sequence would have been—enlarged cervical glands, subsequently infection of the glands in the lungs, and finally infection of the lungs themselves." He also advises that every child suffering from early heart disease should be referred for an opinion whether the tonsils should or should not be enucleated. Breathing exercises, as usually carried out, may sometimes really make matters worse, and require careful watching; the teeth must be set right and the nose kept free from mucus, and every expiration made as complete as possible. As many as 640 throat operations have been done during the year at the Derby and Chesterfield throat clinics, and similar clinics will be opened at other centres shortly. The county council has purchased Bretby Hall and 446 acres of surrounding land for a sanatorium and open-air school for tuberculous and pre-tuberculous children. Dr. Sidney Barwise, who presents this report as school medical officer, repeats his former summing-up, which all medical authorities will heartily endorse, that "by keeping the children's teeth sound, by physical exercises, by open-air schools, and the provision of baths, the bulk of the diseases we now find in the schools would be prevented."

Perth County.

The annual report of the school medical officer shows that out of a school population of 18,288, 8048 children were medically examined during the school year ending July 31st, 1920. Of these 5517 came under the heading of routine inspections, 999 were special cases, and 1532 re-examinations. Eighty per cent. showed defective teeth, while in the same batch of children there were only 7 cases of pronounced rickets and 36 showing slight signs of the disease. Bad vision occurred in 4·9 per cent. of the cases. Dr. D. J. McLeish complains of the inadequacy of physical instruction in the schools. A county organiser of physical education is, however, to be appointed, and this ought to go far to remedy matters. Following up is done in the city of Perth by school nurses, and the children attend clinics for treatment, while in the country districts lists of defects are sent to the district nurse, or failing her to the head teacher, who reports as to whether treatment has been carried out or not. An apparently very necessary campaign against insanitary conditions in the schools is being vigorously carried out in this county.

Liverpool.

Of the 137,430 children on the school rolls at Liverpool in 1919, 27,890 were examined systematically in the code groups of entrants and leavers, as well as 4436 special cases. In the former category the chief defects requiring treatment were those of eyesight (1766) and of the nose and throat (1694); among the children specially examined 1846 and 481 were found to need treatment for these two conditions respectively. The presence of organic heart disease was detected in 52 children (0·018 per cent.) in the code groups; treatment was considered necessary in only 11 cases, the remaining 41 being recommended for observation only. No children were found to be suffering from definite pulmonary tuberculosis needing treatment among the 27,890 systematically examined; 3 only were recommended to be kept under observation; and in addition 12 suspected cases were recommended for treatment. There are, however, 389 children suffering from the pulmonary form excluded from school, but kept under observation, and 378 non-pulmonary cases attending physically defective schools or (if their condition enables them to do so) the ordinary school. Only 59 children (0·21 per cent.) were found to be suffering from malnutrition requiring treatment among the code groups; besides these 182 were kept under observation. Two new clinics were opened during the year, and the total attendances at the five clinics now at work amounted to 80,123, as compared with 26,762 in the previous year. The schools were closed in the early part of the year on account of influenza, and there was also a prevalence of measles and whooping-cough, though less than in 1918. Dr. E. W. Hope, the medical officer of health for the city and school medical officer, refers to an important point in connexion with the treatment of defective eyesight; altogether 2245 new cases were treated, the number having steadily fallen since 1915 (when 5068 were seen), owing to arrears having been gradually overtaken. But "it is still a matter for serious comment that, having obtained glasses, a large proportion of the children do not wear them regularly, even at school." Many glasses get broken, or lost, and are not replaced. If glasses are provided, but not worn, there is a waste of money by the parents, of time and skill by the oculist and optician, and of money, time, and skill of the educational *authority, representing* the whole body of ratepayers. When glasses are not obtained, though prescribed by the oculist, or if obtained not worn, disciplinary measures should be taken to enforce their use in school (which is quite practicable), and every effort made to ensure their use at home, through the agency of the Care Committee. Mr. Alfred Harris, inspector of physical training, shortly describes the excellent work carried on in connexion with the Sports Committee of the Liverpool and District Teachers' Association; amongst many very satisfactory items, not the least is the statement that 3504 swimming certificates were awarded, and of these 667 were won by girls.

Eastbourne.

At Eastbourne Dr. W. G. Willoughby *states that* "the most extensive group of defects is that of the nose and throat, especially enlarged tonsils and adenoids." Out of a total of 1625 children examined in the code groups in 1919—these forming 29·14 per cent. of the number on the registers—no less than 155 were found to require treatment for these affections, and 99 others needed to be kept under observation; 83 other children were specially brought forward to be examined on this account, of whom 65 were recommended for treatment; therefore 15·6 per cent. of the code group children, and 33·6 per cent. of the special cases were considered to be suffering, more or less, from nose and throat defects. This would hardly be expected at a seaside health resort. Only one definite case of pulmonary tuberculosis was found to require treatment; and, though 16 cases of organic heart disease were diagnosed, none were recommended for treatment. There were 55 cases of anæmia, of which 37 were sufficiently marked to need treatment. Dr. Willoughby states that an open-air school is contemplated, which no doubt will benefit these anæmic and tuberculous children. The only other physical *defect of frequent* occurrence was that of vision, 72 children needing glasses among those examined in the code groups, besides 35 others specially brought forward on this account.

URBAN VITAL STATISTICS.

(Week ended Feb. 12th, 1921.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate population estimated at 18½ million persons, the annual rate of mortality, which had been 13·3, 12·3, and 13·1 in the three preceding weeks, rose to 14·0 per 1000. In London, with a population of 4½ million persons, the death-rate was 13·2, against 13·3 per 1000 in the previous week, whilst among the remaining towns the rates ranged from 4·1 in Eastbourne, 5·7 in Dewsbury, and 7·5 in Ealing, to 23·0 in West Hartlepool, 23·4 in South Shields, and 25·7 in Southport. The principal epidemic diseases caused 250 deaths, which corresponded to an annual rate of 0·7 per 1000, and comprised 72 from infantile diarrhœa, 71 from diphtheria, 60 from whooping-cough, 24 from scarlet fever, 19 from measles, and 4 from enteric fever. Whooping-cough caused a death-rate of 1·2 in Swansea and 1·7 in Wigan, and diphtheria of 2·2 in West Bromwich. There were 3945 cases of scarlet fever and 2770 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 4018 and 2767 respectively at the end of the previous week. The causes of 37 of the 4997 deaths in the 96 towns were uncertified, of which 6 were registered in Birmingham, 5 in Gateshead, and 3 each in London and Liverpool. During the week 80 cases of pneumonia, 6 of cerebro-spinal fever, 2 of dysentery, and 22 of encephalitis lethargica were notified in the administrative County of London, as compared with 105, 2, 4, and 29 respectively, in the previous week.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 15·8, 16·3, and 14·9 in the three preceding weeks, rose to 17·4 per 1000. The 380 deaths in Glasgow corresponded to an annual rate of 18·0 per 1000, and included 36 from whooping-cough, 8 from infantile diarrhœa, 5 from diphtheria, and 1 each from small-pox and scarlet fever. The 150 deaths in Edinburgh were equal to a rate of 17·5 per 1000, and included 4 from diphtheria, 3 from whooping-cough, 2 from measles, and 1 each from enteric fever and scarlet fever.

Irish Towns.—The 153 deaths in Dublin corresponded to an annual rate of 18·9, *or 4·8 per 1000 above that recorded* in the previous week, and included 4 each from diphtheria and infantile diarrhœa, and 1 from scarlet fever. The 128 deaths in Belfast were equal to a rate of 15·9 per 1000, and included 13 from whooping-cough.

VITAL STATISTICS OF LONDON DURING JANUARY, 1921.

IN the accompanying table will be found summarised statistics relating to sickness and mortality in the City of London and in each of the metropolitan boroughs. With regard to the notified cases of infectious diseases, it appears that the number of persons reported to be suffering from one or other of the ten diseases notified in the table was equal to an annual rate of 10·4 per 1000 of the population, estimated at 4,531,971 persons in the middle of 1920; in the three preceding months the rates *had been 15·7, 15·2, and 11·9 per 1000.* Among the metropolitan boroughs the lowest rates from these diseases were recorded in Chelsea, the City of Westminster, St. Marylebone, Holborn, the City of London, and Lambeth; and the highest in Bethnal Green, Poplar, Bermondsey, Deptford, Greenwich, and Woolwich. The prevalence of scarlet fever was 17 per cent. less than in the preceding month; this disease was proportionally most prevalent in Hammersmith, Bethnal Green, Poplar, Bermondsey, Deptford, and Woolwich. The Metropolitan Asylums

ANALYSIS OF SICKNESS AND MORTALITY STATISTICS IN LONDON DURING JANUARY, 1921.

* Including membranous croup.

Hospitals contained 4112 scarlet fever patients at the end of the month, against 5117, 5508, and 4729 at the end of the three preceding months; the weekly admissions averaged 489, against 873, 780, and 590 in the three preceding months. Diphtheria was slightly less prevalent than in the preceding month; the greatest proportional prevalence of this disease was recorded in Paddington, Fulham, Islington, Hackney, Bethnal Green, Poplar, Bermondsey, and Greenwich. The number of diphtheria patients under treatment in the Metropolitan Asylums Hospitals, which had been 2284, 2604, and 2615 at the end of the three preceding months, numbered 2648 at the end of January; the weekly admissions averaged 319, against 364, 360, and 316 in the three preceding months. The prevalence of enteric fever was slightly less than in the preceding five months; of the 21 cases notified during the four weeks ended Jan. 29th, 2 belonged to each of the boroughs of Hampstead, St. Pancras, Shoreditch, Wandsworth, and Camberwell. There were 11 cases of enteric fever under treatment in the Metropolitan Asylums Hospitals at the end of the month, against 19, 16, and 15 at the end of the three preceding months; the weekly admissions averaged 3, against 4, 3, and 2 in the three preceding months. Erysipelas was proportionally most prevalent in the City of Westminster, Hackney, Finsbury, Shoreditch, Bethnal Green, and Greenwich. The 37 cases of puerperal fever included 6 in Fulham, 4 in Hackney, 4 in Camberwell, 3 in Hammersmith, and 3 in Woolwich. The 11 cases of cerebro-spinal meningitis included 2 in Fulham and 2 in Hackney; while the one case of poliomyelitis notified during the month belonged to St. Marylebone.

The mortality statistics in the table relate to the deaths of civilians actually belonging to the several boroughs, the deaths occurring in institutions having been distributed among the boroughs in which the deceased persons had previously resided. During the four weeks ended Jan. 29th the deaths of 4348 London residents were registered, equal to an annual rate of 12·5 per 1000; in the three preceding months the rates had been *10·1, 13·1, and 14·2* per 1000. The death-rates ranged from 8·1 in the City of London, 10·3 in Hampstead, 10·4 in Wandsworth, 10·5 in Woolwich, 10·9 in Greenwich, and 11·0 in Camberwell, to in Finsbury, 14·4 in Bermondsey, 15·2 in Stepney, Shoreditch and in Southwark, 15·8 in Kensington, and 16·3 in Chelsea. The 4348 deaths from all causes included 221 deaths which were referred to the principal infectious diseases; of these, 7 resulted from measles, 23 from scarlet fever, 94 from diphtheria, 20 from whooping-cough, 3 from enteric fever, and 74 from diarrhœa and enteritis among children under 2 years of age. No death from any of these diseases was recorded in the City of London or in Greenwich. Among the metropolitan boroughs the lowest death-rates from these diseases were recorded in Chelsea, Hampstead, Holborn, and Woolwich; and the highest in Paddington, Islington, Shoreditch, Stepney, and Poplar. The 7 deaths from measles were less than one-twelfth of the average number in the corresponding period of the five preceding years; of these, 2 belonged to Poplar. The 23 fatal cases of scarlet fever exceeded the average by 12; of these, 4 belonged to Stepney and 2 each to Hammersmith, Islington, Hackney, Bermondsey, Lambeth, Camberwell, and Deptford. The 94 deaths from diphtheria exceeded the average number by 21; the greatest proportional mortality from this disease occurred in Paddington, Fulham, the City of Westminster, Islington, Stoke Newington, Shoreditch, and Poplar. The 20 fatal cases of whooping-cough were less than a third of the average; of these, 3 belonged to Wandsworth and 2 each to St. Pancras, Shoreditch, Battersea, and Camberwell. Three deaths from enteric fever were registered during the month, against an average of 6. The 74 fatal cases of infantile diarrhœa were three in excess of the average number; the greatest proportional mortality from this disease occurred in Paddington, St. Pancras, Bethnal Green, Stepney, Southwark, and Deptford. In conclusion, it may be stated that the aggregate mortality in London during January from these principal infectious diseases was 31 per cent. below the average in the corresponding period of the five preceding years.

SUSSEX EYE HOSPITAL.—The Sussex Eye Hospital has now adopted the principle of paying patients. During the last year 249 in-patients were attended as compared with 244 in the previous year; the out-patients numbered [illegible] against 2572 (attendances 8501); 209 operations were performed against 138; and the casualties attended were [illegible] against 394. There was a loss on the year's working of [illegible]

"Audi alteram partem."

REFERRED PAIN.

THE VISCERO-SENSORY REFLEX IN ABDOMINAL DISEASE.

To the Editor of THE LANCET.

SIR,—I have read with much interest the letter from Dr. A. Murdoch published in your issue of Feb. 5th, in which he criticises the conclusions of your leading article on the subject of Referred Pain in the issue of Jan. 22nd. Sir James Mackenzie and Mr. David Ligat are together responsible for an admirable attempt to simplify all abdominal diagnosis by the discovery of definite areas of hyperalgesia of the skin and subcutaneous tissues of the abdominal wall due primarily to lesions of intra-abdominal organs. It is attractive, it is ingenious, in their hands it may be correct, but does it work out in general clinical experience? My own observations agree with those of Dr. A. F. Hurst, who has doubts as to the reliability of this test.

For a number of years before reading Mr. Ligat's Hunterian lecture I was in the habit of examining all acute abdominal cases by the method of light pin-prick. Then I added his method of pinching up the skin and raising it from the deep fascia, because he suggested that fallacies arose from the methods of observation adopted. My results were just the same, and I found that abdominal cutaneous hyperalgesia, as a clinical sign, was often of value in deciding between the perforation of a gastric as compared with a duodenal ulcer. The former caused hyperalgesia to the left, and the latter to the right, of the middle line. In addition to this, such hyperalgesia was almost invariably present over the appendix area in cases with an acutely inflamed, distended, but non-perforated appendix.

In the case of chronic diseases I have only found this sign to be of value in the presence of distension of the *diseased hollow organs, and I believe that in regarding* distension as the prime cause of abdominal viscero-sensory reflexes I am in accord with Dr. Hurst and other observers. The clinical value of the viscero-motor reflex is fully established, and its presence in duodenal ulcer is of the highest importance.

To explain the existence of the viscero-sensory reflex Sir James Mackenzie postulates the ascension of stimuli from such lesions as ulcers of the stomach and the diffusion of these stimuli amongst the centres of the cord, and this does not tax one's imagination severely, but if it does not work out in clinical experience one may question its correctness. In fact, it is apparently too good to be true, for it would reduce abdominal diagnosis to a childishly simple process of pinching the abdominal wall. When the patient flinched the clinician would only have to look at the chart, as published by Ligat, and the organ diseased would be revealed.

One of the worst fallacies of Ligat's observations, according to my own experience, is the statement that no matter what the anatomical position of the appendix cutaneous hyperalgesia when present is found in the typical area of the right iliac fossa. Such has not been the case with my patients, and several times I have found this cutaneous reflex where the appendix was abnormally placed, but always it has been over the situation of this organ, as revealed by subsequent abdominal section. Mr. Ligat, I believe, in his Hunterian lecture, claimed success for this auxiliary method of diagnosis in a very large proportion of chronic abdominal conditions, but stated that in the acute abdomen its value was apt to be interfered with by the co-existence of peritonitis. Others have considered it of greater value in acute abdominal disease, and I have added above my observations with reference to distension. Distension of a hollow viscus causes traction on the mesenteries which contain its sensory nerves, and thus, I believe, reflexes may be initiated.

As to the statement in Dr. Murdoch's letter that the absence of the sign means nothing, but its presence, even if only noted once, makes all the difference to the diagnosis, this is contrary to our scientific methods of assessing the value of clinical observations. Negatives are surely of the same relative value as positives.

I am, Sir, yours faithfully,

Devonshire-place, W., Feb. 9th, 1921. JOSEPH E. ADAMS.

PS.—This was written before I had read the letter from Dr. J. A. Ryle in your issue of Feb. 12th, but it will be seen how closely we are in clinical agreement.

To the Editor of THE LANCET.

SIR,—In regard to this subject: firstly, do we all mean the same thing when we talk of superficial hyperalgesia? I think not. Some of us mean a definite hyperalgesic area of the skin itself, gentle stroking of which causes pain. That this condition occurs is undoubted, but that it is a rarity is also undoubted. If Dr. J. A. Ryle (Feb. 12th) is referring to this phenomenon when he says that "the superficial hyperæsthesia, which constitutes the reflex, is only present during the presence of pain or for a limited period thereafter," I agree with him and will go further and say that it is very seldom present even then. On the other hand, others of us, when we talk of a hyperalgesic area of the abdominal wall refer to an area of skin *with its underlying subcutaneous tissue;* to test this reflex the skin and subcutaneous tissue must be picked up and pressed between the finger and thumb. In my own experience this functional area is hyperalgesic to pinch in the majority of visceral lesions, excluding those of the large gut, and is of great value in arriving at an exact diagnosis.

If this is the superficial hyperæsthesia which Dr. Ryle refers to I entirely disagree with him when he says that it can only be demonstrated during the presence of pain or for a limited period thereafter. May I quote just one case out of many in support of this?—

A young medical man whom I knew, acting as house surgeon in a London hospital, was a thorough sceptic in regard to the clinical value of the functional area reflex. He joined up during the war. Some time after his discharge he called on me, and he mentioned that about six months previously he had had a sharp attack of appendicitis, but had not had his appendix removed as the conditions at the time were unfavourable. Asked if he had had it out after leaving the army, he said: "No; as I haven't had the slightest pain or discomfort for months, I don't think it is going to worry me again." I asked him to allow me to examine his abdominal reflexes. He laughed, but said I might. I picked up the skin and subcutaneous tissue in the left hypochondriac region and pressed it firmly. He smiled. I did exactly the same to his appendix functional area. He cried out with pain. Two days after his late chief removed a red, swollen appendix.

In my experience the test thus applied evokes the reflex so constantly in visceral lesions that it is a matter for surprise when one fails to find it. I have little doubt but that this reflex could have been elicited in seven or eight of the ten cases which Dr. A. F. Hurst has mentioned, but I should have been surprised had he found the purely cutaneous reflex in any of them, as I think its incidence in such cases (presumably cases of chronic gastric ulcer) is nearer 1 per cent. than 10.

I am, Sir, yours faithfully,

D. LIGAT.

Devonshire-street, Portland-place, W., Feb. 14th, 1921.

PSEUDO-COXALGIA.

To the Editor of THE LANCET.

SIR,—Mr. H. A. T. Fairbank has performed important service in directing attention in THE LANCET (Jan. 1st) to the condition called, amongst other names, "Pseudo-coxalgia," and outlining the differential diagnosis between it and tuberculous disease of the hip-joint. It is remarkable that while well recognised on the continent and in America, it has attracted little attention in this country, and is not diagnosed by the majority of surgeons and practitioners, but confused with tuberculous arthritis of the hip.

In the X ray room of the Treloar Cripples' Hospital at Alton I always have a skiagram illustrating the condition on view, and have been struck by the rarity with which the disease is recognised by English medical colleagues, while it is almost invariably immediately diagnosed by medical visitors from abroad. The condition is undoubtedly much commoner than might be supposed, and it may be of interest to call attention to its incidence by giving the numbers of cases admitted to Alton during the years 1918, 1919, 1920 :—

Year.	No. of cases of alleged tuberculous disease of hip.	Pseudo-coxalgia.	*Percentage.*
1918	67	3	4·4
1919	95	3	3·1
1920	89	6	6·7
—	251	12	4·8

The diagnosis in each case was confirmed by X ray examination. In every case the patient was sent in as suffering from tuberculous disease of the hip-joint, and the majority of cases were transferred from other hospitals.

It may be assumed that these cases are: (1) frequently incorrectly diagnosed; and (2) that the relative incidence is greater than in the figures obtainable from Alton. The second assumption I base on the following grounds. In the majority of cases of tuberculous arthritis sent to Alton the disease is acute, cases which rapidly improve with domiciliary or general hospital treatment rarely reach us, and in many cases application for admission is withdrawn before orders for admission are sent if the patient is not found to require further institutional treatment. It may also, I think, be a reasonable inference to make that no inconsiderable proportion of patients with alleged tuberculous disease of the hip-joint who rapidly improve under treatment or without treatment are in reality suffering from pseudo-coxalgia, and that many patients whose mysteriously rapid recovery has puzzled their medical attendants belong to this group. There remains, however, a residuum of patients with pseudo-coxalgia in whom the condition is acute and continues so for some months with considerable muscular spasm, and where clinical diagnosis from tuberculous disease of the hip-joint may be difficult, though radiographic examination will always afford certain differentiation. For these, recumbency and extension of the leg on the affected side with attempted gradual abduction is the treatment which I have found most efficacious, and I continue such treatment until the sign of activity in tuberculous disease of the hip-joint, which I have already described, is no longer present.[1] Finally, recognising that damage has been done to the head of the femur, I, with Mr. Fairbank, do not consider it wise to allow the patient to walk at first without removing pressure from the hip-joint on the affected side, though in place of the calliper splint he advocates I usually substitute the splint here described, which I have also often found useful in the ambulatory treatment of tuberculous disease of the hip-joint when that disease is no longer acute. Essentially the splint is as follows: A flexible strip of sheet iron suitably padded passes round the pelvis below the iliac crests, but above the great trochanters, and is buckled in front. Posteriorly, two padded pieces of duralumin are fixed to the pelvic band and moulded on to the ischial tuberosities. These effectually prevent the pelvic band from being displaced upwards. Finally, from the posterior part of the pelvic band immediately behind the great trochanter and extending vertically downwards is an extensible and adjustable duralumin rod, expanding outwards to firmly grip the femoral condyles of the affected limb. The weight of the body is thus taken off the hip-joint on the affected side and transmitted via the ischial tuberosity. This apparatus is simple and efficacious.

In your issue of Jan. 8th you again refer to the condition in an annotation under the heading "Quiet Hip Disease." In the present state of our knowledge I confess I cannot as yet agree with the views on the ætiology of the condition therein ascribed to Dr. Sundt. Sundt and Legg both consider that trauma is the cause and that the condition is not due to infection. Clinical considerations and X ray findings, to my mind, do not compel such a view, and I cannot but think that trauma plays no greater a part in pseudo-coxalgia than it does in tuberculosis of the hip-joint. In further support of this statement I would record that many of my patients have been cachectic and appeared to be suffering from some toxæmia. I do not know what the causal agent can be, *but it may not be without some significance that* in three out of my last 30 cases, the notes of which I have looked up, the Wassermann test was positive. Of these 30 cases (22 hospital and eight private), when treatment was sought at Alton or I was consulted privately, the average age was 8 years, the youngest patient was aged 4 years, the oldest 12 years. The average duration of symptoms before I saw the patient was 13 months, the shortest one month, the longest four years. In 15 cases the right hip was affected, in 13 cases the left, and in two cases both hips. Five of these patients were girls, 25 were boys. This latter observation might be considered to favour the traumatic theory of origin. Incidentally, "flat-headed femur," the most expressive name I have heard given to the condition, hails from America.

With other observers, I would agree that the condition always progresses towards recovery. As far as I am aware, no directly fatal case has ever been recorded, nor is permanent disability, other than slight shortening and limitation of abduction, to be anticipated. Nevertheless, in a few cases the condition may remain acute and be associated with pain, tenderness, and muscular spasm, for some months, and call for recumbent treatment as already outlined. I have two such cases under my care at the moment. In one, a boy, tuberculous disease of the hip-joint was diagnosed two and a half years before admission to Alton. He was treated at two separate hospitals, from both of which he was discharged as cured. At his third relapse he was sent to Alton. On admission he was markedly cachectic, and his general appearance was consistent with an active case of tuberculous disease of the hip-joint. The affected limb was slightly flexed, but further flexion to a right angle was possible, though painful, abduction and rotation of the limb very limited. The muscular spasm was relieved by extension and the limb straightened, but ambulatory treatment was accompanied by return of the symptoms. The patient is now at ease in a plaster spica, but remains cachectic. The other active case now under treatment was similarly admitted with symptoms of acute disease and similar limitation of movement and was also markedly cachectic. Shortly after admission she *developed acute abdominal pain simulating* appendicitis, which was in due course relieved without operative interference. This was probably not secondary to the pseudo-coxalgia. She is still being treated recumbently and with extension, the condition is still active, but less acute, and she has less cachexia.

The further contribution by Dr. H. B. Roderick on this interesting condition in THE LANCET (Jan. 29th) is a valuable one. Dr. Roderick's argument that the disease may be caused by circulatory disturbance secondary to trauma is a well-reasoned and weighty one. He, however, has laid little stress on changes which radiography shows take place in the femoral neck, and does not explain the apparent shortening and marked thickening of the neck of the femur often observed. On my last admission day, Jan. 27th, I took in at Alton 10 cases of alleged tuberculous disease of the hip-joint. Of these, two have proved to be cases of Legg's disease. The first, a boy aged 8 years, was admitted with suspected tuberculous disease of the left hip-joint. He proves to be a case of double pseudo-coxalgia. The second, a girl aged 13 years, has had symptoms suggestive of tuberculous disease of the right hip for the last nine months, and has *also been* treated as tuberculous.

I am, Sir, yours faithfully,
HENRY J. GAUVAIN.
Harley-street, W., Feb. 11th, 1921.

---

[1] Sign of Pathological Activity in Tuberculous Disease of the Hip. H. J. Gauvain, THE LANCET, Nov. 20th, 1915.

DANGEROUS DRUGS ACT, 1920.

To the Editor of THE LANCET.

SIR,—The Medical Benefit Subcommittee of the Insurance Committee for the Borough of Brighton have had before them, and have very carefully considered, the provisions of the draft Regulations proposed to be issued by the Secretary of State for Home Affairs under the above Act. As a result of this consideration the Subcommittee passed the following resolutions:—

> (*a*) "That the Secretary of State for Home Affairs be informed that the procedure which it is required in compliance with the proposed Regulations that insurance practitioners should adopt will prove, under the unnecessary official interference with everyday practice, so irksome to practitioners, that it will be detrimental to the interests of the insured person, inasmuch as the consequence will be, in many cases, to deprive the insured person of the drug which may be necessary and which would otherwise be given, and further, if such drug is prescribed, its required advertisement on the bottle or package will have a harmful effect on the patient in many cases."
>
> (*b*) "That the insurance practitioner should be allowed, as heretofore, every latitude in determining the drugs considered most desirable for his insurance patient without having to disclose to lay inspecting officials professional matters and should be responsible to the Minister of Health alone for his actions in this direction."

In the discussion which took place the main points which were emphasised are as follows:—

1. Article 8 (8) of the terms of service for insurance practitioners stipulates:—

> "A practitioner is required to supply to a patient where requisite drugs and appliances, which are necessarily or ordinarily administered by a practitioner in person, or are needed for immediate administration or application, or needed for use before a supply can conveniently be obtained otherwise under the Regulations."

It would appear from the rather vague terms of the draft Regulations, that on every occasion upon which an insurance practitioner is under the necessity of complying with the obligations undertaken as a consequence of the foregoing article he must make, or cause to be made, in a book kept for the purpose, specific and detailed, and, indeed, somewhat laboured entries, if the particular drug comes within the scope of these proposed Regulations. It is strongly felt that this would be detrimental to the interests of insured persons, inasmuch as the practitioner, rather than comply with the irksome necessary clerical procedure, may refrain from giving the necessary drug. I am aware that Sir Edward Troup, Permanent Under Secretary at the Home Office, in a letter which appeared in the *Times* on Feb. 9th, wrote as follows:—

> "In several important respects the draft Regulations have been misunderstood. It has been suggested, for instance, that a doctor is required on each occasion on which he gives a hypodermic injection of morphia or otherwise administers any of the drugs to enter the fact in a book. This is not so. The Regulations require certain records to be kept in cases where drugs are supplied, and these apply to doctors who supply medicines to their patients, as well as to chemists who supply them on a doctor's prescription. But there is no requirement that a record has to be kept of a personal administration of the drugs by a doctor."

If Sir Edward Troup's interpretation on this point is the correct one, then it is respectfully submitted that the draft Regulations should be so amended as to make the matter quite clear.

2. Provided an insurance practitioner has occasion to prescribe medicines containing an amount beyond the statutory limit of any of the drugs set forth in the proposed Regulations then the fact must be advertised on the bottle or package containing such drugs. Indeed, the Article defining the "application" of the Regulations in connexion with morphine, cocaine, ecgonine, and diamorphine, when read in conjunction with Article (8) of the Regulations, is rather confusing. However, it is suggested that a bottle or package which loudly proclaims to the insured person the fact that it contains a certain percentage of a dangerous drug is not conducive to that serene frame of mind which in the interests of the patient himself his medical attendant would wish *him* to cultivate.

It is hoped that your influential paper will support the views above expressed, and make every endeavour to get the proposed Regulations so amended as to entirely safeguard the interests of the country's insured population.—I am, Sir, yours faithfully,

JNO. CAMPBELL,
Acting Clerk to the Brighton Insurance Committee.
Brighton, Feb. 11th, 1921.

PROPHYLAXIS AND VENEREAL DISEASE.

To the Editor of THE LANCET.

SIR,—Mr. Kenneth M. Walker, supposing that "it is only over the question of prophylaxis that the split has arisen" between the National Council for Combating Venereal Diseases and the Society for the Prevention of Venereal Disease in your issue of Feb. 5th, says:—

> "...I put forward a suggestion that has already been made. Is it asking too much that members of the two societies should arrange to meet? Surely it is better that differences of opinion should be amicably discussed in a meeting of medical men rather than be made the subject of a bitter and somewhat tedious correspondence in the press."

I fear, however, that more than medical men are involved in this matter and that more separates the two societies than the mere question of prophylaxis. Very grave accusations have been made. The S.P.V.D. is pressing for a public inquiry into the past on the grounds that the truth has been suppressed both during and since the war, that the Ministry of Health itself has issued misleading statistics with comments equally misleading, and that the careers of public officials have depended on considerations other than efficient performance of duty. I need not expatiate on all this; I have dealt with it elsewhere; but, obviously, if these things are believed, those who credit them can feel no safety about the future until there has been an authoritative inquiry into the past. If the N.C.C.V.D. will join the S.P.V.D. in pressing for such an independent inquiry, I feel sure that all differences, if not of opinion, at least of policy, will be eliminated.

May I thank your reviewer for his most kind and indulgent review of my book? But will he please forgive me just one comment? He writes:

> "In conclusion, we hope that when the second edition of this work appears its author will see his way to eliminate certain personal though anonymous references, which, in lack of taste, afford a striking contrast to an otherwise powerfully written and valuable volume."

But if the statements I have made be true, how is it possible to avoid these personal references? Events do not happen of themselves. Even the reviewer, when alluding to the Inter-Departmental Committee, makes just such personal references.

I am, Sir, yours faithfully,
Southsea, Feb. 10th, 1921. G. ARCHDALL REID.

To the Editor of THE LANCET.

SIR,—My Executive Committee, at their meeting on Feb. 10th, requested me to inform your readers that Mr. Kenneth Walker's statements in his letter published in your issue of Feb. 5th, regarding the policy of the Society for the Prevention of Venereal Disease, were incorrect, and evidently based on a misapprehension of the origin and scope of our society. This society was founded solely to fill in the gap in the propaganda of the National Council for Combating Venereal Diseases left by their opposition to instruction of the public in the prevention of infection by means of immediate self-disinfection. My society, while freely acknowledging that immediate self-disinfection is only one of many methods for diminishing venereal disease, believe that this method is an extremely important and valuable one, and our propaganda is devoted solely to bringing this method before the public, not because we are in any way whatever antagonistic to other methods, but because this method was not only neglected, but actively opposed by the N.C.C.V.D. Our work is not in opposition to but complementary to that of the National Council.

In order to obviate overlapping we confine our work to giving publicity to the one method not included in the useful and widespread propaganda of the N.C.C.V.D. The suggestion that we "regard it [i.e., immediate self-disinfection] as the single measure that will cure our ills" is therefore founded on ignorance of our published statements. Again, we have times without number pointed out that we do not advocate the packet system, and in our letter published in the *Times* of Oct. 13th, 1919, which defined our policy, we stated:—

> "We decline to accept the description of our policy as the issue of prophylactic packets to the civilian community in the way in which they were issued to H.M. Forces. No suggestion has yet

been made by our committee as to the methods or means by which the public may obtain the necessary disinfecting material, the fact that such materials are easily obtained at any chemist being in our opinion quite sufficient. The aim of the committee is solely the instruction of the public."

Mr. Walker has summed up our wishes in his sentence, "let each of the societies work along the line it has chosen." My society would welcome the teachers of moral prevention as allies working along another line towards the same goal, if they on their part would accept the alliance of the teachers of medical prevention and not waste valuable energy in opposition that is not only unnecessary but also hopeless as long as disinfectants are acknowledged to disinfect. As regards Mr. Walker's suggested meeting between the two societies, official correspondence between the presidents of the two societies with this object occurred not long after the foundation of our society in 1919. My society stated their willingness to meet the National Council in conference if the National Council would accept and endorse the principles and practice of immediate self-disinfection as one of the valuable methods of preventing venereal infection. This the National Council were unable to do, and therefore the conference fell through. Our offer to meet the National Council on these grounds has never been withdrawn.—I am, Sir, yours faithfully,

H. WANSEY BAYLY,
Honorary Secretary, Society for the Prevention of Venereal Disease.

143, Harley-street, W., Feb. 12th, 1921.

CONGENITAL SYPHILIS AMONG THE NEWLY BORN.

To the Editor of THE LANCET.

SIR,—In your issue of Feb. 12th Dr. S. M. Ross and Dr. A. F. Wright, in an article under this heading, seem to quote me in support of their statement that an estimate of the amount of congenital syphilis among the newly born, based upon Wassermann reactions upon the umbilical cord serum, will be lower than is actually the case. This is the exact opposite of the impression I wished to convey in the paper they referred to. I showed that a positive Wassermann reaction at birth in most cases merely indicated that the mother had a positive reaction, which passed passively into the infant. If the infant was tested a short time after birth it was found to have a negative reaction. Thus a test of the umbilical cord serum cannot be taken as an indication of syphilis in the infant and estimates of incidence based upon such tests will be *much too high.*

Since my paper was published in 1915 I have seen this umbilical cord reaction quoted as evidence of the ravages of syphilis, and, further, such "syphilitic" infants have been "cured" with remarkable facility with salvarsan. It has always seemed to me that this test introduces a gross error into the work of infant welfare organisations so far as syphilis is concerned. No one can take exception to the conclusions of the present authors, but it is to be hoped that orators will not quote them as saying that 3·5 per cent. of infants are syphilitic.—I am, Sir, yours faithfully,

P. FILDES.

London Hospital, E., Feb. 11th, 1921.

THE INDICATIONS FOR REMOVAL OF TONSILS.

To the Editor of THE LANCET.

SIR,—With reference to recent correspondence in THE LANCET on this subject, I am of opinion, after considerable experience, that the following conclusions are justified: 1. That in children practically all tonsils can be enucleated readily and easily with the guillotine. 2. That in adults they are better removed by a dissection operation. I personally use a McKenzie separator. Provided sufficient care is taken to hit the capsule the operation is easy. But in both cases a very great deal depends upon the skill of the anæsthetist. The latter should not only be able to control the patient's head, but he should know his operator's methods well enough as to reciprocate him.

I am, Sir, yours faithfully,
MACLEOD YEARSLEY.

lbeck-street, Cavendish-square, W., Feb. 15th, 1921.

THE OPERATIVE TREATMENT OF PROLAPSE.

To the Editor of THE LANCET.

SIR,—I am surprised to find from Mr. A. H. Burgess's letter in THE LANCET last week that he is still using paraffin wax injections for prolapse. At one time the method was popular, but, as there were so many bad results from it, I thought it had been entirely discarded. I have never used it myself, not liking the idea of introducing a foreign mass into the pelvis, which cannot be removed. But I have seen the secondary results in quite a number of cases, and these included large pelvic abscesses, often months after the injection of the paraffin, and one of the worst tunnel strictures I ever saw. The stricture case proved to be hopeless, as the mass of paraffin wax prohibited all efforts to dilate the stricture, and the patient had to have a colostomy performed. The great objection to the wax treatment is that if anything goes wrong the mass cannot be removed.

I cannot understand Mr. Burgess's argument about primary union, as, surely, with primary union no adhesions are formed. My reason for using healing by granulation in these cases is that firm adhesions between the rectal and the pelvic walls are produced —the condition which is required to hold up the prolapse; stitching the rectum to the sacrum and pelvic wall is not possible, and this method has proved a very satisfactory alternative. If the surgeon is for some reason unable to stitch up a hernial ring, or otherwise to close the opening, he will find that leaving the wound to close by granulation is a satisfactory substitute, although, of course, inferior to stitching up the parts. All I claim is that where, as in the case of prolapse, stitching is useless, the method I employ is a very satisfactory substitute—and the value of an operation depends upon the results obtained. I have treated 32 cases by this method, with only one complete failure. I am surprised that Mr. Burgess has had no failures after paraffin wax injections, and should like to know his figures.—I am, Sir, yours faithfully,

J. P. LOCKHART-MUMMERY, F.R.C.S.

London, Feb. 15th, 1921.

THE DEVELOPMENT OF STUMPS.

To the Editor of THE LANCET.

SIR,—Many surgeons of the limb-fitting centres of the United Kingdom find, after performing a very successful amputation or re-amputation of a limb, that their patients, on being fitted with artificial limbs, fail utterly to carry them, either through muscular weakness, awkwardness, or shrinkage of the stump. The surgeon naturally turns to massage and stump exercises for a remedy. These exercises are usually carried out against resistance, and to a certain extent do some good, but i is necessary to call to one's aid the brain of the patient I make a practice of asking the patient to concentrat his mind on the foot or hand, as the case may be, o the limb he has lost. He at first finds this mental co centration hard to acquire, but once it is established h can contract muscles at the end of his stump whic would be impossible without mentally attaching to h limb the distal member which has been amputate Take, for example, a below-the-knee amputation, upp third. If the patient is asked to extend his leg wi the toes pointing to the ground, both vasti will thrown into a far greater state of contraction than th obtained by the present faulty system of exercis Now in this same amputation, if the patient is asked flex and extend the foot at the ankle-joint, and a evert and invert the foot, the end of the stump will seen dimpling owing to the action of the musc brought into play by movements at the ankle-joint.

The advantage of this system of exercises will quickly seen in the tone of the muscles and nouri ment of the stump. In educating the patient in t remembrance of the distal end of the amputated li the tone and development of the muscles are retain The strength of the voluntary muscles is fully doubl The artificial limb becomes animate and equilibriu established.—I am, Sir, yours faithfully,

M. DOCKRELL, L.R.C.P. & S. Irel.
Special Surgical Hospital, Blackrock, co. Dub
Ministry of Pensions.

Feb. 14th, 1921.

Medical News.

UNIVERSITY OF CAMBRIDGE.—In accordance with the decision of the Senate on Jan. 28th the General Board of Studies have appointed Dr. C. S. Myers, F.R.S., as Reader in Experimental Psychology for five years from Oct. 1st last. The University Lectureship in Experimental Psychology has been held by Dr. Myers since 1907.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—An ordinary Council meeting was held on Feb. 10th, with Sir Anthony Bowlby in the chair.—A report was read from the Court of Examiners respecting candidates found qualified for the diploma of Member, and diplomas were granted to 84 candidates mentioned in the report.—A report was read from the secretary of the Conjoint Examining Board respecting candidates found qualified for the diploma in Ophthalmic Medicine and Surgery of the two Colleges, and diplomas were granted jointly with the Royal College of Physicians to seven candidates mentioned in the report.—Dr. W. S. A. Griffith was reappointed the representative of the College on the Central Midwives Board for one year from March 31st, 1921, and a vote of thanks was passed to him for his services on the Board during the past year.—A letter was read from the Registrar of the General Medical Council calling attention to the fact that on and after Jan. 1st, 1923, all those who desire to be registered as medical or dental students will have to produce evidence that they have attained the age of 17 years, and that the minimum standard of general education required will be that of university matriculation or entrance examination; that before registration as a medical student every applicant will be required to have passed in addition to the examination in general education, an examination in elementary physics and elementary chemistry conducted or recognised by one of the licensing bodies, and that a student who has diligently attended an approved course of instruction in elementary biology at a secondary school or other teaching institution recognised by a licensing body may be admitted to the professional examination in elementary biology immediately after his registration as a student. The matter was referred to the Dental Board and the Committee of Management of the Conjoint Board.—A memorial was read from the Section of Otology of the Royal Society of Medicine, asking the Royal Colleges to grant a diploma in the science and art of otology. The matter was referred to the Committee of Management of the Conjoint Board.—A letter was read from the Voluntary Hospital Committee appointed by the Minister of Health to inquire into the financial position of the voluntary hospitals and to make recommendations, asking whether the Royal College of Surgeons desires to present any evidence to the Committee. The President, with Mr. H. J. Waring, Mr. Raymond Johnson, and Sir Cuthbert Wallace were appointed to consider the matter.—Sir Charles Ballance reported to the Council on his recent visit to Egypt for the purpose of inspecting the Cairo School of Medicine.—The President reported that a meeting of the Fellows would be held at the College on Thursday, July 7th next, for the election of four Fellows into the Council in the vacancies occasioned by the retirement in rotation of Sir George H. Makins, Mr. J. Ernest Lane, Mr. H. J. Waring, and Mr. F. F. Burghard; that notice of the meeting would be given to Fellows by advertisement and by circular on March 11th; that March 21st would be the last day for the nomination of candidates; and that a voting paper would be sent on April 5th to every Fellow of the College whose address is registered at the College.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—At a meeting of Comitia of the Royal College of Physicians on Feb. 3rd and of the Council of the Royal College of Surgeons on Feb. 10th diplomas of L.R.C.P. and M.R.C.S. were conferred upon 84 candidates (including 16 women) who have passed the Final Examination in Medicine, Surgery, and Midwifery of the Conjoint Board, and have complied with the by-laws of the Colleges. The following are the names and medical schools of the successful candidates:—

Doris Elizabeth Alcock, Royal Free Hosp.; H. E. Alexander, Pennsylvania University; G. W. Almeyda, London Hosp.; C. H. Andrewes and H. N. Andrewes, St. Bart.'s Hosp.; Kathleen Ardell, Royal Free Hosp.; O. A. Baker, W. E. Barnes, and H. E. Beasley, Univ. Coll. Hosp.; *Evelyn Frances Bebbington, Liverpool University; Margaret Gladys Best, St. Mary's Hosp.; L. M. Billingham, St. Bart.'s Hosp.; I. Blain, Manchester University; C. H. Bracewell and J. L. M. Brown, St. Bart.'s Hosp.; R. Buddle, Otago University; C. L. C. Burns, St. Thomas's Hosp.; A. Y. Cantin, Paris and London Hosp.; Dorothy Spencer Chamberlain, King's Coll. Hosp.; L. C. F. Chevens, St. Thomas's Hosp.; F. Christian, Univ. Coll. Hosp.; Ivy Collier, St. Mary's Hosp.; F. P. de Caux, St. Bart.'s Hosp.; A. H. G. Down, Univ. Coll. Hosp.; A. O. Duncan, London Hosp.; T. A. Eccles, St. Bart.'s Hosp.; R. T. Edwards, London Hosp.; H. Franklyn, Cambridge University and St. Bart.'s Hosp.; O. P. Gallegos, Charing Cross Hosp.; G. I. Griffiths, Liverpool University; W. R. W. Haight, Toronto University; H. W. Hammond, St. Bart.'s Hosp.; Katharine May Harbord, Royal Free Hosp.; H. J. B. Hendley, St. Bart.'s Hosp.; T. B. Hodgson, Oxford University and St. Bart.'s Hosp.; S. H. G. Humfrey, Cambridge University and St. Thomas's Hosp.; A. Y. Ibrahim, St. Thomas's Hosp.; J. G. Johnstone, Oxford University and St. Bart.'s Hosp.; H. C. V. Joy, London Hosp.; A. N. Kingsbury, Middlesex Hosp.; F. G. Latham, Liverpool University; Anna Gwenllian Mary Lewis, Univ. Coll. Hosp.; C. J. Lewis, Birmingham University; C. A. Lindup, Univ. Coll. Hosp.; Kathleen Maria Boyce McArthur, Cambridge and St. Mary's Hosp.; H. McKenzie, London Hosp.; Elizabeth Matthai, Royal Free Hosp.; A. Mikhail, Guy's Hosp.; G. S. Mitchell, Westminster Hosp.; W. P. Newman, St. Thomas's Hosp.; Helen O'Brien, Royal Free and St. Mary's Hosps.; F. R. Oliver and S. Orchard, Cambridge University and St. Bart.'s Hosp.; T. L. Ormerod, St. Bart.'s Hosp.; Tresilla Laura Pires, Charing Cross Hosp.; Olive Gwendoline Potter, London Hosp.; C. S. C. Prance, St. Bart.'s Hosp.; I. M. Rattray, St. George's Hosp.; P. L. Richardson, Guy's Hosp.; O. A. L. Roberts, St. Mary's Hosp.; A. R. Roushdy, Charing Cross Hosp.; G. R. A. de M. Rudolf, King's Coll. Hosp.; H. L. Sackett, St. Bart.'s Hosp.; A. R. Sami, St. Thomas's Hosp.; Maud Sanderson, St. Mary's Hosp.; R. G. V. Shaw, Sydney University and London Hosp.; N. L. Shoorey, Bombay University and London Hosp.; E. A. Sparks, St. Thomas's Hosp.; H. Spibey, Univ. Coll. Hosp.; J. A. Stephens, Leeds University; R. N. L. Symes, St. Thomas's Hosp.; A. H. Talaat, Middlesex Hosp., K. H. Tallerman, Cambridge University and St. Thomas's Hosp.; H. E. Thomas, Univ. Coll. Hosp.; J. S. Thomas, London Hosp.; N. G. Thomson, Cambridge University and St. Bart.'s Hosp.; H. M. Toop, London Hosp.; G. D. C. Tracy, Cambridge University and St. Thomas's Hosp.; T. W. Turner, Guy's Hosp.; Madeline Hilda Jane Umpleby, St. George's Hosp.; Gladys Mary Wauhope, St. Andrews University and London Hosp.; May Grant Williams, Royal Free Hosp.; H. N. Witham, St. Thomas's Hosp.; and F. W. Zaglama, Manchester University.

* Diploma of M.R.C.S. alone conferred.

ROYAL INSTITUTION OF GREAT BRITAIN.—On Tuesday, Feb. 22nd, at 3 P.M., Professor Arthur Keith, F.R.S., will give the first of four lectures on Darwin's Theory of Man's Origin (in the Light of Present-day Evidence).

SOCIETY OF M.O.H.: SCHOOL MEDICAL SERVICE GROUP.—A meeting of the Group Council will be held to-day, Saturday, at 11 A.M., and of the Group at 11.30 A.M. at 1, Upper Montague-street, Russell-square, London, W.C. The subjects for discussion are (1) Uniformity of Medical Inspection Cards and Schedules and (2) Superannuation and Security of Tenure. Members of the school medical service who are not members of the society will be welcome as visitors. Suggestions for papers or notice of any other matter of special interest to the service will be welcomed by the honorary secretary, Dr. Armly Ashkenny, Health Department, West Bromwich.

THE HORSLEY MEMORIAL.—The executive committee of this Fund publish the following second list of subscriptions:—

	£	s.	d.
Mr. and Mrs. Edward Robinson	105	0	0
Sir F. W. Chance	20	0	0
Dr. W. S. Coleman, Mr. A. H. Burgess, Mr. C. H. Carlisle ... ... each	10	10	0
Miss M. W. Ranken	10	0	0
Sir Berkeley Moynihan, Sir A. Pearce Gould, Dr. J. Smith Whitaker, Dr. F. J. Hopkinson, Mr. Wilfred Trotter, Miss Mary Robinson, Miss Margaret Knowles ... each	5	5	0
Mrs. Scharlieb, M.D., Mrs. Rosa Napier, Miss Emily Chaplin ... ... each	5	0	0
Sir Thomas Barlow, Sir Humphry D. Rolleston, Mr. Harry Platt, Dr. Thomas Wilson, Mrs. Frances Levy, Dr. Thomas W. Thomas, Dr. W. H. Rivers, Anonymous (per Dr. Collier) ... ... each	3	3	0
Sir William Macewen, Dr. E. Rowland Fothergill, Right Rev. Dr. Hine, Dr. May Thorne, Sir Squire Sprigge, Mrs. Henry Fawcett, Mr. J. H. Morgan, Dr. George Pernet, Professor James Sully, Dr. J. A. Macdonald, Dr. Edwin Bramwell, Mr. J. Furneaux Jordan, Mr. J. H. Bown, Professor W. D. Halliburton ... ... each	2	2	0
Lady Rhondda, Dr. Joyce, Dr. Wallace Henry, Professor Keith, Sister Newill, Sister Frinzeauma Low, P. Maud Webbe and A. J. Webbe, Canon J. W. Horsley, Mr. C. W. Beresford, Mrs. E. J. Dawson, Miss Juliet Simons, Dr. Herbert Jones, Dr. Harriette Chick ... ... each	1	1	0
Miss T. R. Murray	1	0	0
Mrs. Lindo Henry...	0	10	6
Mr. George E. Abbot	0	10	0
Dutch Branch of the International League against Epilepsy (per Dr. Muskens, Amsterdam)			

The amount acknowledged in the first list (THE LANCET, Jan. 1st, p. 46) was £324 17s., and in that list "Sir Charles Harrison" should read "Sir Cecil Harrison, K.B.E." Further subscriptions may be sent to the honorary treasurers, Sir Frederick Mott, K.B.E., Maudsley Neurological Hospital, Denmark Hill, S.E. 5, and Dr. Howard Tooth, C.B., C.M.G., 34, Harley-street, W. 1, or the honorary secretaries, Sir W. Arbuthnot Lane, Bart., C.B., and Edward J. Domville, O.B.E., Shutes, Symondsbury, Bridport.

Obituary.

WILLIAM LATTO ROBERTSON, *M.C.*, M.B., CH.B. EDIN., F.R.C.S. EDIN., &c.,

CAPTAIN, R.A.M.C.

William Latto Robertson, who died on Jan. 24th from blood poisoning, the result of puncturing his finger while performing an operation at the Royal Infirmary, Dundee, during the previous week, was educated at the High School, Dundee, and at St. Andrews University, where he graduated M.A. In 1905 he graduated M.B., Ch.B., at Edinburgh University, in which year he also took the L.R.C.P., L.R.C.S. Edin., L.R.F.P.S. Glasg. Following qualification he held residential appointments at the Chalmers' Hospital, the Royal Infirmary, and the Royal Hospital for Sick Children, Edinburgh, and, after visiting various clinics abroad, joined Mr. D. M. Greig in his private surgical practice as assistant at Dundee in 1907. In that year he obtained the F.R.C.S. Edin. Subsequently he became assistant surgeon at Dundee Royal Infirmary and clinical tutor at St. Andrews University. On the outbreak of war Captain Robertson went with the 3rd Highland Field Ambulance to France, was mentioned in despatches on two occasions, and in 1918 was awarded the Military Cross. After acting as D.A.D.M.S. he was transferred to Italy, where he later acted as A.D.M.S., with the rank of lieutenant-colonel. On resuming practice in Dundee he was appointed full surgeon at the Royal Infirmary, and in December of last year a lecturer in clinical surgery at St. Andrews University and Dundee University College. Captain Robertson had an engaging and modest personality; his death at the age of 38 years has cut short the promise of a successful surgical career.

THE LATE DR. EDWARD BUCKELL.—Dr. Edward Buckell, who died at Brighton on Feb. 5th at the age of 94, had lived in retirement for many years. He qualified M.R.C.S.Eng. and L.S.A. as long ago as 1849 from University College Hospital, where he was one of those present on Dec. 21st, 1846, at the first operation performed under ether in Europe—an amputation of the leg by Robert Liston. He spent the best part of his professional life at Winchester, where he practised for 26 years, and was district medical officer to the Winchester Union. Dr. Buckell was a son of the late Mr. John Westmore Buckell, of Chichester, where members of his family are still in practice.

THE LATE DR. J. C. MCWALTER.—The death of Dr. J. C. McWalter in Dublin on Feb. 8th was announced in our columns last week. He was only 50 years of age, and appeared in good health, but on the evening previous to his death, as the sequel of a hurried walk of two miles, he showed signs of collapse on reaching home. Under medical attention he appeared to recover, but later his heart failed again, and death followed shortly. Dr. McWalter was a man of great energy and versatility. A medical man in busy practice, interested in all professional affairs, a member of the Corporation of Dublin, attending to his duties with scrupulous care, chairman of many committees, an indefatigable writer of letters, notes, and articles to the medical and lay papers, he yet found time to read for qualifications beyond count. Possessed of degrees in medicine, arts, or law of four universities, and diplomas from three corporations, he was also a barrister-at-law and a civil engineer. During the war he served as a captain in the R.A.M.C., most of his foreign service being in the Mediterranean area. He was High Sheriff of Dublin at the time of his sudden death.

THE LATE DR. FRANCIS WILLIAM DAVIDSON.—The death took place at Banchory on Feb. 10th of Dr. Francis W. Davidson, late of Thornton Heath, Surrey. Dr. Davidson, who was 38 years of age, was a son of the late Mr. Alex. D. Davidson, of London. He was educated at the Grammar School and University of Aberdeen, where he graduated M.B., Ch.B., in 1904. On leaving the university he held the appointments of house physician and house surgeon at the Royal Hospital, Richmond, and afterwards joined his elder brother, the late Dr. James Gellie Davidson, in practice at Thornton Heath. The brothers built up an extensive practice, assisted later by a third brother, also a graduate of Aberdeen, Dr. R. Gibson Davidson. Dr. F. W. Davidson once contributed to THE LANCET (1910, ii., 1276) an account of a remarkable case, which should have attracted [illegible] tion than it apparently did, of concurrent extra- and intra-uterine pregnancy. A ruptured ectopic gestation was diagnosed by him, and on operation two fœtuses of about two months development were found. Six months after a normal full-term child was delivered at term. Dr. Davidson joined the R.A.M.C. during the war, and served in Egypt. In December last, on account of failing health, he sold his practice and went to live in Banchory. His interests outside medicine were many—music, art, and architecture, and he was learned upon the structures of old cathedrals and churches. Dr. Davidson was unmarried, and is survived by his mother, brother, and sister.

THE LATE MR. J. D. STAPLE.—The death occurred suddenly on Feb. 4th, from cerebral hæmorrhage, of James Dibble Staple, M.R.C.S.Eng., L.S.A., at Lyme Regis, where he had been residing for the past five years. Mr. Staple was born at Crewkerne, being the only son of members of two old Somersetshire families. After being educated at private schools and abroad, he studied at Westminster Hospital and took the qualifications of L.S.A. in 1884 and M.R.C.S. in 1887. After holding appointments as house surgeon at Plymouth, Norwich, and Stockport, he settled in Bristol, where he resided for 30 years and acquired a very extensive practice, for 20 years being medical officer for No. 3 District and public vaccinator for the Ashley District of the Bristol Union. In 1916, owing to failing health, Mr. Staple went to Lyme Regis, where he was still able to do a small amount of medical work up to and including the day of his death. Mr. Staple was of a genial and sympathetic nature and much beloved by his patients and friends, by whom he will be greatly missed.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

J. St. B. Crosbie is granted a commission as Surgeon-Lieutenant.

ROYAL ARMY MEDICAL CORPS.

Lieut.-Col. J. Grech retires on retired pay and is granted the rank of Colonel.

The undermentioned relinquish the acting rank of Lieutenant-Colonel: Capt. and Bt. Major R. E. Barnsley and Major C. R. M. Morris.

Temp. Capts. C. F. Strange (retains the rank of Captain) and F. W. H. Pilot relinquish their commissions.

SPECIAL RESERVE OF OFFICERS.

The undermentioned Captains relinquish their commissions and retain the rank of Captain: W. Buchan, V. D. Wyborn, D. Roger, E. S. Davies, A. J. Macartney, and C. B. Dyson.

TERRITORIAL FORCE.

Major W. T. Rowe to be Lieutenant-Colonel and command 3rd Northern Casualty Clearing Station.

Capt. G. T. Willan to be Major.

Capt. A. C. MacDonald (late R.A.M.C., S.R.) to be Captain.

ROYAL AIR FORCE.

The undermentioned are granted short service commissions as Flight Lieutenants, retaining their present seniority: S. E. Duff and C. McC. Jones.

Flight Lieutenant R. Mugliston resigns his short service commission and is permitted to retain the rank of Captain.

INDIA AND THE INDIAN MEDICAL SERVICE.

Capt. J. Horn has been appointed Temporary Director of the Pasteur Institute. Lieut.-Col. T. Hunter has been appointed Civil Surgeon from Mussoorie to Bareilly. Lieut.-Col. W. Battye, on return from leave, has been posted as Residency Surgeon at Hyderabad. Major T. A. Hughes has been appointed Professor of Physiology, Medical College, Lahore. Major M. R. C. MacWalters, professor of surgery, Medical College, Lucknow, has been granted six months' leave. During his absence Lieut.-Col. Barnardo will have entire charge of Simla. Lieut.-Col. Watson has been posted as Civil Surgeon at Ajmer. Lieut.-Col. McGaw has been declared a member of the United Provinces Medical Council. Major C. L. Dunn, on return from leave, resumes his duties as Sanitary Commissioner, United Provinces. Major A. E. J. Lister, professor, King George Medical College, has been granted leave on a medical certificate. Lieut. C. L. Amenrand to hold Civil Medical Charge of Raniket in addition to his duties, vice Capt. R. Hemphill, D.S.O., R.A.M.C. Lieut.-Col. T. Hunter has been appointed Civil Surgeon, Mussoorie, on completion of his special duty. Major A. S. Fry has relinquished charge of the duties of medical officer, Seistan. Major A. H. Napier, military medical officer, to have Charge of Roorkee, vice Capt. H. K. Diskehit. Major R. A. Chambers assumes charge of office of Principal Medical School, Amritzar.

ST. MARK'S HOSPITAL.—The annual meeting was held at the Mansion House on Feb. 10th. In the unavoidable absence of the Lord Mayor, Colonel Sheriff Wishart took the chair on his behalf. The report showed that £1200 had been raised towards the much-needed improvement of the nurses' quarters, but that a balance of £800 was still required. During the past year 630 in-patients had been under treatment, and 1510 out-patients made 4576 attendances.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY, Burlington House, London, W.

Thursday, Feb. 24th.—Papers:—Sir Ray Lankester: A Remarkable Flint Implement from Selsey Bill.—Dr. E. J. Allen: Regeneration and Reproduction of the Syllid Procerastea.—Mr. E. C. Grey and Mr. E. G. Young: The Enzymes of *B. Coli Communis*. Part. II., (*a*) Anaerobic Growth followed by Anaerobic and Aerobic Fermentation; (*b*) The Effects of Aeration during the Fermentation (communicated by Prof. F. G. Hopkins).—Dr. A. E. Everest and Mr. A. J. Hall: Anthocyanins and Anthocyanidins. Part IV. (communicated by Prof. F. Keeble).

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, Feb. 22nd.

SECTION OF MEDICINE: at Guy's Hospital, S.E.

Tea and Demonstrations (at 4–5.30 P.M.):

Dr. G. H. Hunt: An Experimental Oxygen Chamber.

Dr. G. K. Marshall: Apparatus for Induction of Artificial Pneumothorax.

Dr. G. H. Hunt and Dr. E. P. Poulton: Congenital Heart Disease with Analysis of Arterial Blood.

Dr. C. P. Symonds: A Case of Charcot-Marie-Tooth Muscular Dystrophy with Pseudo-hypertrophy.

And other Demonstrations by the Physicians and Assistant Physicians.

At 5.30 P.M.:

Dr. G. H. Hunt: Cardiac Efficiency in Normal and Pathological Conditions.

Mr. J. M. H. Campbell: Factors in the Causation of Dyspnœa.

Dr. J. A. Ryle: The Diagnostic Value and the Limitations of the Fractional Test-meal.

Will Members intending to come to tea kindly notify Dr. Poulton at Guy's Hospital not later than Feb. 20th.

Thursday, Feb. 24th.

SECTION OF TROPICAL MEDICINE: at 5 P.M.

Election of Officers and Council for the current Session.

Presidential Address by Sir Leonard Rogers, C.I.E.

Paper: Dr. J. Gordon Thomson and Dr. A. Robertson: The Value of Laboratory Reports in the Diagnosis of Suspected Dysentery, and their Interpretation by the Clinician.

Demonstrations by Professor Leiper and others.

SECTION OF UROLOGY: at 8.30 P.M.

CLINICAL and PATHOLOGICAL EVENING.

Specimens will be shown by—

Mr. Jocelyn Swan: Angeioma of Kidney.

Mr. Girling Ball: Hæmatoma of Kidney.

Will Members desiring to show specimens similar to the above please communicate with the Hon. Secretary, Mr. Cyril A. R. Nitch, 69, Harley-street, W. 1.

Friday, Feb 25th.

SECTION OF STUDY OF DISEASE IN CHILDREN: at 4.30 P.M. (instead of 5 P.M.)

Discussion: On "The Diagnosis and Treatment of Congenital Syphilis and its Effects."

To be opened by Sir Humphry Rolleston and Mr. O. L. Addison, followed by Dr. Findlay, Dr. Nabarro, and others.

CLINICAL SECTION
SECTION OF MEDICINE } ADJOURNED JOINT MEETING: at 8.30 P.M.
SECTION OF SURGERY

Discussion: On "The Medical and Surgical Treatment of Graves' Disease" (to be reopened by Mr. Donald Armour, Dr. J. M. H. Campbell, Mr. W. H. C. Romanis, Mr. A. J. Walton, Professor Earle, and others.

SECTION OF EPIDEMIOLOGY AND STATE MEDICINE: at 8.30 P.M.

Paper: Dr. R. M. F. Picken: The Epidemiology of Measles in a Rural and Residential Area.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

Monday, Feb. 21st.—9 P.M., Lettsomian Lecture (II.):—Mr. G. E. Gask: Surgery of the Lung and Pleura.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.

Monday, Feb. 21st.—5 P.M., Arris and Gale Lecture:—Prof. J. Howell Evans: The Azygos System of Veins in their Association with Surgical Affections.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

Monday, Feb. 21st.—2 P.M., Mr. B. Harman: Eye Department. Dr. Simson: Diseases of Women. 2.30 P.M., Mr. Baldwin: Visit to Surgical Wards. 5 P.M., Lecture:—Dr. G. Stewart: Locomotor Ataxia.

Tuesday.—10 A.M., Mr. Steadman: Dental Department. Dr. McDougall: Electrical Department. 12 noon, Mr. T. Gray: Demonstration of Fractures. 5 P.M., Lecture:—Dr. Burnford: Investigation of the Functions of the Digestive Tract.

Wednesday.—10 A.M., Mr. MacDonald: Genito-Urinary Department. 12 noon, Mr. Sinclair: Surgical Diseases of the Abdomen. 2 P.M., Mr. Gibb: Eye Department. 5 P.M., Lecture:—Mr. D. Armour: Physical Signs and Diagnosis of Abdominal Tumours.

Thursday.—2 P.M., Dr. S. Pinchin: Medical Out-patients. Mr. Baldwin: Orthopædic Department. Mr. D. Armour: Operations. 5 P.M., Special Lecture:—Mr. S. Edwards: Points in Rectal Surgery (open to all medical practitioners).

Friday.—10 A.M., Mr. D. Buxton: Dental Department. 2 P.M., Mr. Banks Davis: Diseases of the Throat, Nose, and Ear. Dr. Pernet: Skin Department. 5 P.M., Lecture:—Mr. Addison: Carcinoma of the Breast.

Saturday.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 2 P.M., Dr. Owen: Medical Out-patients.

Daily:—10 A.M. Ward Visits. 2 P.M., In-patient, Out-patient Clinics and Operations.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Monday, Feb. 21st.—10 A.M., Mr. W. E. Tanner: Surgical Out-patients. 2 P.M.; Dr. A. J. Whiting: Medical In-patients. 2.30 P.M., Mr. E. Gillespie: Surgical Operations. Mr. J. B. Banister: Gynæcological Out-patients. Dr. J. B. Alexander: Medical Out-patients. 4.30 P.M., Clinical Demonstration:—Dr. J. B. Alexander: Cases of Medical Interest. 6 P.M., Dr. F. L. Provis and Mr. T. H. C. Benians: Venereal Department.

Tuesday.—9.45 A.M., Lieut.-Col. R. H. Elliot and Mr. N. Fleming: Eye Operations. 2.30 P.M., Mr. H. W. Carson: Surgical Operations. Mr. C. H. Hayton: Diseases of the Throat, Nose, and Ear. Dr. Metcalfe: X Ray Department. 3 P.M., Clinical Demonstration:—Mr. C. H. Hayton: Lupus of Nose and Pharynx. 5.30 P.M., Dr. C. E. Sundell: Children In-patients.

Wednesday.—2 P.M., Mr. C. H. Hayton: Throat Operations. 2.30 P.M., Dr. W. J. Oliver: Skin Department. Dr. J. B. Alexander: Medical Out-patients. 4.30 P.M., Clinical Demonstration:—Mr. N. Fleming: Cases of Eye Disease. 5 P.M., Dr. Provis and Mr. Benians: Venereal Department.

Thursday.—2 P.M., Mr. N. Fleming: Eye Out-patients. 2.30 P.M., Dr. A. J. Whiting: Medical Out-patients. Mr. H. W. Carson: Surgical Out-patients. Mr. J. B. Banister: Gynæcological Operations. Dr. J. Metcalfe: X Ray Department. 3 P.M., Clinical Demonstration:—Dr. J. Metcalfe: Treatment by Ionic Medication.

Friday.—2 P.M., Mr. Howell Evans: Surgical Operations. 2.30 P.M., Dr. C. E. Sundell: Children Out-patients. Mr. E. Gillespie: Surgical Out-patients. 4.30 P.M., Clinical Demonstration:—Dr. R. M. Leslie: Selected Medical Cases. 5 P.M., Dr. Provis and Mr. Benians: Venereal Department.

Saturday.—3 P.M., Mr. H. W. Carson: Surgical In-patients.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, W.C. 1.

MEDICAL SCHOOL.

Monday, Feb. 21st.—2 P.M., Out-patient Clinic: Dr. Collier. 3.30 P.M., Lecture:—Dr. Kinnier Wilson: Hysteria and its Treatment.

Tuesday, Feb. 22nd.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Lecture:—Dr. Collier: Diseases of the Cranial Nerves.

Thursday, Feb. 24th.—2 P.M., Out-patient Clinic: Dr. Farquhar Buzzard. 3.30 P.M., Lecture:—Mr. Scott: Disturbances of the Vestibular System. (I.)

Friday, Feb. 25th.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Lecture:—Dr. Grainger Stewart: Affections of the Pituitary Gland.

Fee for Post-Graduate Course £7 7s. C. M. Hinds Howell, Dean.

MIDDLESEX HOSPITAL MEDICAL SCHOOL (University of London).

Tuesday, Feb. 22nd.—3 P.M., Emeritus Lecture:—Sir Alfred Pearce Gould: Surgery.

KING'S COLLEGE (Department of Science), Strand.

Nine Lectures on Problems of Modern Science.

Wednesday, Feb. 23rd.—5.15 P.M., Lecture (VI.):—Prof. A. Dendy: Biology.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

Thursday, Feb. 24th.—4 P.M., Lecture:—Dr. T. Thompson: Neuritis.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westmoreland-street, W.

Monday, Feb. 21st.—5.30 P.M., Post-Graduate Lecture:—Dr. P. Hamill: Myocardial Disease.

Thursday, Feb. 24th.—6 P.M., Chesterfield Lecture:—Dr. W. Griffith: Diseases of the Skin Appendages.

ROYAL INSTITUTION OF GREAT BRITAIN, Albemarle-street, Piccadilly, W.

Tuesday, Feb. 22nd.—3 P.M., Lecture:—Prof. A. Keith: Darwin's *Theory of Man's Origin*.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

Tuesday, Feb. 22nd.—4.30 P.M., Lecture:—Mr. P. R. Wrigley: Cholecystitis.

SALFORD ROYAL HOSPITAL AND ANCOATS HOSPITAL POST-GRADUATE DEMONSTRATIONS, at the two Hospitals alternately.

Thursday, Feb. 24th.—4.30 P.M., Dr. Stirling: Common Eye Diseases and their Treatment. (At Ancoats Hospital.)

ST. MARY'S HOSPITALS, MANCHESTER, POST-GRADUATE LECTURE, at Whitworth-street West Branch.

Friday, Feb. 25th.—4.30 P.M., Dr. Lacey: The Toxæmias of Pregnancy.

MANCHESTER BABIES' HOSPITAL.

Post-Graduate Lectures and Demonstrations in the Onward Buildings, Deansgate, or at the Hospital, Slade lane.

Saturday, Feb. 26th.—3.30 P.M., Dr. Chisholm: Demonstration of Differing Types of the Non-Thriving Infant. (At the Babies' Hospital.)

MANCHESTER FRENCH HOSPITAL POST-GRADUATE LECTURES, 24, Acomb-street, Whitworth Park.

Thursday, Feb. 24th.—4.30 P.M., Dr. A. C. Magian: Some Chronic Uterine Diseases and their Treatment.

Obituary.

WILLIAM LATTO ROBERTSON, *M.C.*, M.B., CH.B. EDIN., F.R.C.S. EDIN., &c.,

CAPTAIN, R.A.M.C.

William Latto Robertson, who died on Jan. 24th from blood poisoning, the result of puncturing his finger while performing an operation at the Royal Infirmary, Dundee, during the previous week, was educated at the High School, Dundee, and at St. Andrews University, where he graduated M.A. In 1905 he graduated M.B., Ch.B., at Edinburgh University, in which year he also took the L.R.C.P., L.R.C.S. Edin., L.R.F.P.S. Glasg. Following qualification he held residential appointments at the Chalmers' Hospital, the Royal Infirmary, and the Royal Hospital for Sick Children, Edinburgh, and, after visiting various clinics abroad, joined Mr. D. M. Greig in his private surgical practice as assistant at Dundee in 1907. In that year he obtained the F.R.C.S. Edin. Subsequently he became assistant surgeon at Dundee Royal Infirmary and clinical tutor at St. Andrews University. On the outbreak of war Captain Robertson went with the 3rd Highland Field Ambulance to France, was mentioned in despatches on two occasions, and in 1918 was awarded the Military Cross. After acting as D.A.D.M.S. he was transferred to Italy, where he later acted as A.D.M.S., with the rank of lieutenant-colonel. On resuming practice in Dundee he was appointed full surgeon at the Royal Infirmary, and in December of last year a lecturer in clinical surgery at St. Andrews University and Dundee University College. Captain Robertson had an engaging and modest personality; his death at the age of 38 years has cut short the promise of a successful surgical career.

THE LATE DR. EDWARD BUCKELL.—Dr. Edward Buckell, who died at Brighton on Feb. 5th at the age of 94, had lived in retirement for many years. He qualified M.R.C.S. Eng. and L.S.A. as long ago as 1849 from University College Hospital, where he was one of those present on Dec. 21st, 1846, at the first operation performed under ether in Europe—an amputation of the leg by Robert Liston. He spent the best part of his professional life at Winchester, where he practised for 26 years, and was district medical officer to the Winchester Union. Dr. Buckell was a son of the late Mr. John Westmore Buckell, of Chichester, where members of his family are still in practice.

THE LATE DR. J. C. MCWALTER.—The death of Dr. J. C. McWalter in Dublin on Feb. 8th was announced in our columns last week. He was only 50 years of age, and appeared in good health, but on the evening previous to his death, as the sequel of a hurried walk of two miles, he showed signs of collapse on reaching home. Under medical attention he appeared to recover, but later his heart failed again, and death followed shortly. Dr. McWalter was a man of great energy and versatility. A medical man in busy practice, interested in all professional affairs, a member of the Corporation of Dublin, attending to his duties with scrupulous care, chairman of many committees, an indefatigable writer of letters, notes, and articles to the medical and lay papers, he yet found time to read for qualifications beyond count. Possessed of degrees in medicine, arts, or law of four universities, and diplomas from three corporations, he was also a barrister-at-law and a civil engineer. During the war he served as a captain in the R.A.M.C., most of his foreign service being in the Mediterranean area. He was High Sheriff of Dublin at the time of his sudden death.

THE LATE DR. FRANCIS WILLIAM DAVIDSON.—The death took place at Banchory on Feb. 10th of Dr. Francis W. Davidson, late of Thornton Heath, Surrey. Dr. Davidson, who was 38 years of age, was a son of the late Mr. Alex. D. Davidson, of London. He was educated at the Grammar School and University of Aberdeen, where he graduated M.B., Ch.B., in 1904. On leaving the university he held the appointments of house physician and house surgeon at the Royal Hospital, Richmond, and afterwards joined his elder brother, the late Dr. James Gellie Davidson, in practice at Thornton Heath. The brothers built up an extensive practice, assisted later by a third brother, also a graduate of Aberdeen, Dr. R. Gibson Davidson. Dr. F. W. Davidson once contributed to THE LANCET (1910, ii., 1276) an account of a remarkable case, which should have attracted more attention than it apparently did, of concurrent extra- and intra-uterine pregnancy. A ruptured ectopic gestation was diagnosed by him, and on operation two fœtuses of about two months development were found. Six months after a normal full-term child was delivered at term. Dr. Davidson joined the R.A.M.C. during the war, and served in Egypt. In December last, on account of failing health, he sold his practice and went to live in Banchory. His interests outside medicine were many—music, art, and architecture, and he was learned upon the structures of old cathedrals and churches. Dr. Davidson was unmarried, and is survived by his mother, brother, and sister.

THE LATE MR. J. D. STAPLE.—The death occurred suddenly on Feb. 4th, from cerebral hæmorrhage, of James Dibble Staple, M.R.C.S. Eng., L.S.A., at Lyme Regis, where he had been residing for the past five years. Mr. Staple was born at Crewkerne, being the only son of members of two old Somersetshire families. After being educated at private schools and abroad, he studied at Westminster Hospital and took the qualifications of L.S.A. in 1884 and M.R.C.S. in 1887. After holding appointments as house surgeon at Plymouth, Norwich, and Stockport, he settled in Bristol, where he resided for 30 years and acquired a very extensive practice, for 20 years being medical officer for No. 3 District and public vaccinator for the Ashley District of the Bristol Union. In 1916, owing to failing health, Mr. Staple went to Lyme Regis, where he was still able to do a small amount of medical work up to and including the day of his death. Mr. Staple was of a genial and sympathetic nature and much beloved by his patients and friends, by whom he will be greatly missed.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

J. St. B. Crosbie is granted a commission as Surgeon-Lieutenant.

ROYAL ARMY MEDICAL CORPS.

Lieut.-Col. J. Grech retires on retired pay and is granted the rank of Colonel.

The undermentioned relinquish the acting rank of Lieutenant-Colonel: Capt. and Bt. Major R. E. Barnsley and Major C. R. M. Morris.

Temp. Capts. C. F. Strange (retains the rank of Captain) and F. W. H. Pilot relinquish their commissions.

SPECIAL RESERVE OF OFFICERS.

The undermentioned Captains relinquish their commissions and retain the rank of Captain: W. Buchan, V. D. Wyborn, D. Roger, E. S. Davies, A. J. Macartney, and C. B. Dyson.

TERRITORIAL FORCE.

Major W. T. Rowe to be Lieutenant-Colonel and command 3rd Northern Casualty Clearing Station.

Capt. G. T. Willan to be Major.

Capt. A. C. MacDonald (late R.A.M.C., S.R.) to be Captain.

ROYAL AIR FORCE.

The undermentioned are granted short service commissions as Flight Lieutenants, retaining their present seniority: S. E. Duff and C. McC. Jones.

Flight Lieutenant R. Mugliston resigns his short service commission and is permitted to retain the rank of Captain.

INDIA AND THE INDIAN MEDICAL SERVICE.

Capt. J. Horn has been appointed Temporary Director of the Pasteur Institute. Lieut.-Col. T. Hunter has been appointed Civil Surgeon from Mussoorie to Bareilly. Lieut.-Col. W. Battye, on return from leave, has been posted as Residency Surgeon at Hyderabad. Major T. A. Hughes has been appointed Professor of Physiology, Medical College, Lahore. Major M. R. C. MacWalters, professor of surgery, Medical College, Lucknow, has been granted six months' leave. During his absence Lieut.-Col. Barnards will have entire charge of Simla. Lieut.-Col. Watson has been posted as Civil Surgeon at Ajmer. Lieut.-Col. McGaw has been declared a member of the United Provinces Medical Council. Major C. L. Dunn, on return from leave, resumes his duties as Sanitary Commissioner, United Provinces. Major A. E. J. Lister, professor, King George Medical College, has been granted leave on a medical certificate. Lieut. C. L. Amenrand to hold Civil Medical Charge of Raniket in addition to his duties, vice Capt. R. Hemphill, D.S.O., R.A.M.C. Lieut.-Col. T. Hunter has been appointed Civil Surgeon, Mussoorie, on completion of his special duty. Major A. S. Fry has relinquished charge of the duties of medical officer, Seistan. Major A. H. Napier, military medical officer, to have Charge of Roorkee, vice Capt. H. K. Diskshit. Major R. A. Chambers assumes charge of office of Principal Medical School, Amritzar.

ST. MARK'S HOSPITAL.—The annual meeting was held at the Mansion House on Feb. 10th. In the unavoidable absence of the Lord Mayor, Colonel Sheriff Wishart took the chair on his behalf. The report showed that £1200 had been raised towards the much-needed improvement of the nurses' quarters, but that a balance of £800 was still required. During the past year 630 in-patients had been under treatment, and 1510 out-patients made 4576 attendances.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY, Burlington House, London, W.

Thursday, Feb. 24th.—Papers:—Sir Ray Lankester: A Remarkable Flint Implement from Selsey Bill.—Dr. E. J. Allen: Regeneration and Reproduction of the Syllid Procerastea.—Mr. E. C. Grey and Mr. E. G. Young: The Enzymes of *B. Coli Communis.* Part. II., (*a*) Anaerobic Growth followed *by Anaerobic* and Aerobic Fermentation; (*b*) The Effects of Aeration during the Fermentation (communicated by Prof. F. G. Hopkins).—Dr. A. E. Everest and Mr. A. J. Hall: Anthocyanins and Anthocyanidins. Part IV. (communicated by Prof. F. Keeble).

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, Feb. 22nd.

SECTION OF MEDICINE: at Guy's Hospital, S.E.

Tea and Demonstrations (at 4-5.30 P.M.):

Dr. G. H. Hunt: An Experimental Oxygen Chamber.

Dr. G. K. Marshall: Apparatus for Induction of Artificial Pneumothorax.

Dr. G. H. Hunt and Dr. E. P. Poulton: Congenital Heart Disease with Analysis of Arterial Blood.

Dr. C. P. Symonds: A Case of Charcot-Marie-Tooth Muscular Dystrophy with Pseudo-hypertrophy.

And other Demonstrations by the Physicians and Assistant Physicians.

At 5.30 P.M.:

Dr. G. H. Hunt: Cardiac Efficiency in Normal and Pathological Conditions.

Mr. J. M. H. Campbell: Factors in the Causation of Dyspnœa.

Dr. J. A. Ryle: The Diagnostic Value and the Limitations of the Fractional Test-meal.

Will Members intending to come to tea kindly notify Dr. Poulton at Guy's Hospital not later than Feb. 20th.

Thursday, Feb. 24th.

SECTION OF TROPICAL MEDICINE: at 5 P.M.

Election of Officers and Council for the current Session.

Presidential Address by Sir Leonard Rogers, C.I.E.

Paper: Dr. J. Gordon Thomson and Dr. A. Robertson: The Value of Laboratory Reports in the Diagnosis of Suspected Dysentery, and their Interpretation by the Clinician.

Demonstrations by Professor Leiper and others.

SECTION OF UROLOGY: at 8.30 P.M.

Clinical and Pathological Evening.

Specimens will be shown by—

Mr. Jocelyn Swan: Angeioma of Kidney.

Mr. Girling Ball: Hæmatoma of Kidney.

Will Members desiring to show specimens similar to the above please communicate with the Hon. Secretary, Mr. Cyril A. R. Nitch, 69, Harley-street, W. 1.

Friday, Feb 25th.

SECTION OF STUDY OF *DISEASE IN CHILDREN*: at 4.30 P.M. (instead of 5 P.M.)

Discussion: On "The Diagnosis and Treatment of Congenital Syphilis and its Effects."

To be opened by Sir Humphry Rolleston and Mr. O. L. Addison, followed by Dr. Findlay, Dr. Nabarro, and others.

CLINICAL SECTION
SECTION OF MEDICINE } Adjourned Joint Meeting: at 8.30 P.M.
SECTION OF SURGERY

Discussion: On "The Medical and Surgical Treatment of Graves' Disease" (to be reopened by Mr. Donald Armour, Dr. J. M. H. Campbell, Mr. W. H. C. Romanis, Mr. A. J. Walton, Professor Earle, and others.

SECTION OF EPIDEMIOLOGY AND STATE MEDICINE: at 8.30 P.M.

Paper: Dr. R. M. F. Picken. The Epidemiology of Measles in a Rural and Residential Area.

MEDICAL SOCIETY OF LONDON, 11, *Chandos-street, Cavendish-square, W.*

Monday, Feb. 21st.—9 P.M., Lettsomian Lecture (II.):—Mr. G. E. Gask: Surgery of the Lung and Pleura.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.

Monday, Feb. 21st.—5 P.M., Arris and Gale Lecture:—Prof. J. Howell Evans: The Azygos System of Veins in their Association with Surgical Affections.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

Monday, Feb. 21st.—2 P.M., *Mr. B. Harman: Eye Department.* Dr. Simson: Diseases of Women. 2.30 P.M., Mr. Baldwin: Visit to Surgical Wards. 5 P.M., Lecture:—Dr. G. Stewart: Locomotor Ataxia.

Tuesday.—10 A.M., Mr. Steadman: Dental Department. Dr. McDougall: Electrical Department. 12 noon, Mr. T. Gray: Demonstration of Fractures 5 P.M., Lecture:—Dr. Burnford: Investigation of the Functions of the Digestive Tract.

Wednesday.—10 A.M., Mr. MacDonald: Genito-Urinary Department. 12 noon, Mr. Sinclair: Surgical Diseases of the Abdomen. 2 P.M., Mr. Gibb: Eye Department. 5 P.M., Lecture:—Mr. D. Armour: Physical Signs and Diagnosis of Abdominal Tumours.

Thursday.—2 P.M., Dr. S. Pinchin: Medical Out-patients. Mr. Baldwin: Orthopædic *Department. Mr. D. Armour: Operations.* 5 P.M., Special Lecture:—Mr. S. Edwards: Points in Rectal Surgery (open to all medical practitioners).

Friday.—10 A.M., Mr. D. Buxton: Dental Department. 2 P.M., Mr. Banks Davis: Diseases of the Throat, Nose, and Ear. Dr. Pernet: Skin Department. 5 P.M., Lecture:—Mr. Addison: Carcinoma of the Breast.

Saturday.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 2 P.M., Dr. Owen: Medical Out-patients.

Daily:—10 A.M. Ward Visits. 2 P.M., In-patient, Out-patient Clinics and Operations.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Monday, Feb. 21st.—10 A.M., Mr. W. E. Tanner: Surgical Out-patients. 2 P.M., Dr. A. J. Whiting: Medical In-patients. 2.30 P.M., Mr. E. Gillespie: Surgical Operations. Mr. J. B. Banister: Gynæcological Out-patients. Dr. J. B. Alexander: Medical Out-patients. 4.30 P.M., Clinical Demonstration:—Dr. J. B. Alexander: Cases of Medical Interest. 6 P.M., Dr. *F. L. Provis and Mr. T. H. C. Benians: Venereal Department.*

Tuesday.—9.45 A.M., Lieut.-Col. R. H. Elliot and Mr. N. Fleming: Eye Operations. 2.30 P.M., Mr. H. W. Carson: Surgical Operations. Mr. C. H. Hayton: Diseases of the Throat, Nose, and Ear. Dr. Metcalfe: X Ray Department. 3 P.M., Clinical Demonstration:—Mr. C. H. Hayton: Lupus of Nose and Pharynx. 5.30 P.M., Dr. C. E. Sundell: Children In-patients.

Wednesday.—2 P.M., Mr. C. H. Hayton: Throat Operations. 2.30 *P.M., Dr. W. J. Oliver: Skin Department. Dr. J. B.* Alexander: Medical Out-patients. 4.30 P.M., Clinical Demonstration:—Mr. N. Fleming: Cases of Eye Disease. 5 P.M., Dr. Provis and Mr. Benians: Venereal Department.

Thursday.—2 P.M., Mr. N. Fleming: Eye Out-patients. 2.30 P.M., Dr. A. J. Whiting: Medical Out-patients. Mr. H. W. Carson: Surgical Out-patients. Mr. J. B. Banister: Gynæcological Operations. Dr. J. Metcalfe: X Ray Department. 3 P.M., Clinical Demonstration:—Dr. J. Metcalfe: Treatment by *Ionic Medication.*

Friday.—2 P.M., Mr. Howell Evans: Surgical Operations. 2.30 P.M., Dr. C. E. Sundell: Children Out-patients. Mr. E. Gillespie: Surgical Out-patients. 4.30 P.M., Clinical Demonstration:—Dr. R. M. Leslie: Selected Medical Cases. 5 P.M., Dr. Provis and Mr. Benians: Venereal Department.

Saturday.—3 P.M., Mr. H. W. Carson: Surgical In-patients.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, W.C. 1.

MEDICAL SCHOOL.

Monday, Feb. 21st.—2 P.M., Out-patient Clinic: Dr. Collier. 3.30 P.M., Lecture:—Dr. Kinnier Wilson: Hysteria and its Treatment.

Tuesday, *Feb. 22nd.—2 P.M., Out-patient Clinic:* Dr. Grainger Stewart. 3.30 P.M., Lecture:—Dr. Collier: Diseases of the Cranial Nerves.

Thursday, Feb. 24th.—2 P.M., Out-patient Clinic: Dr. Farquhar Buzzard. 3.30 P.M., Lecture:—Mr. Scott: Disturbances of the Vestibular System. (I.)

Friday, Feb. 25th.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Lecture:—Dr. Grainger Stewart: Affections of the Pituitary Gland.

Fee for Post-Graduate Course £7 7s. C. M. Hinds Howell, Dean.

MIDDLESEX HOSPITAL MEDICAL SCHOOL (University of London).

Tuesday, Feb. 22nd.—3 P.M., Emeritus Lecture:—Sir Alfred Pearçe Gould: Surgery.

KING'S COLLEGE (Department of Science), Strand.

DICK.—On Feb. 6th, at Beaufort House, Grange Park, Ealing, the wife of Major A. M. Dick, F.R.C.S., I.M.S., of a daughter.

TAYLOR.—On Feb. 7th, at Wayland House, Bridlington, the wife of C. R. Taylor, O.B.E., M.B., B.Ch. Cantab., of a daughter.

WILLCOCKS.—On Feb. 10th, in Sydney, to George C. Willcocks, M.R.C.P., F.R.C.S., and Hilda (née Richards) Willcocks, L.R.C.P., M.R.C.S.—a son.

MARRIAGES.

COVENTON—OSTLE.—On Jan. 29th, at St. Bartholomew's-the-Less, E.C., Albert William Duncan Coventon, M.B., to Helen Muriel, youngest daughter of the late Rev. W. and Mrs. Ostle.

POOLE—BUCHANAN.—On Feb. 5th, at St. Martin's-in-the-Fields, Frank Stedman Poole, M.R.C.S., L.R.C.P., to Marjorie, younger daughter of Mr. and Mrs. James Buchanan, of Drayton-gardens, S.W.

DEATHS.

TOMLINSON.—On Feb. 8th, at Sparth Hall, Stockport, John Tomlinson, M.R.C.S., in his 90th year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Communications, Letters, &c., to the Editor have been received from—

Notes, Short Comments, and Answers to Correspondents.

KINEMATOGRAPH ILLUMINATION:

THE USE AND ABUSE OF LIGHT IN STUDIOS FOR KINEMA FILM PRODUCTION.[1]

BY J. C. ELVY, A.M.I.E.E.,
CONSULTING ENGINEER.

The Lighting Equipment of Kinema Studios.

THERE are a number of points to be considered in the lighting equipment of a kinema studio. The essential factors are the actinic values of the various lighting units available, the amount of electrical energy required to operate them, the initial cost of the equipment, and the cost of maintenance. The question of illumination and its relationship to the sensitiveness of both the photographic film and the physiological system is now gaining the prominence it deserves.

Eyesight Troubles in Kinema Studios.

It is now more than a year ago since I referred to the possibility of eyesight trouble in kinema studios, arising from the special lighting conditions employed. The eye has been developed under conditions of natural lighting which involve only moderate intrinsic brilliances. The accompanying table shows the intrinsic brilliances of various illuminants:—

Source of light.	Candle-power per sq. in.	Source of light.	Candle-power per sq. in.
Uniform white sky...	2·5	Flame arc	5,000
Oil lamp	3—5	Open arc	10,000—50,000
Mercury vapour lamp	15—20	Open arc (crater)	200,000
Enclosed arc	100—500	Sun...	500,000—600,000
Gas-filled tungsten filament lamp ...	2200		

This table alone suffices to show the great differences between the conditions when a film is taken in the open air by the natural light of the white sky, and by powerful arc lamps at close quarters.

There seems to be a general impression that the main source of eyesight trouble in studios, when it occurs, is the exposure to sources of very great intrinsic brilliancy. It is possible that the strong ultra-violet component in some lights, may accentuate a tendency to inflammation of the eyes, as it has been remarked in other processes—e.g., in arc-welding, &c. Inflammation or scorching of the skin which accompanies eye irritation in some cases is also a well-known result of excessive exposure to ultra-violet light. Again, prolonged exposure to light of a peculiar colour may lead to subsequent derangement of colour vision. Professor Burch, by exposure of his own eye to intense monochromatic light, produced disturbances which persisted for more than a year. These are questions on which the coöperation of ophthalmologists is necessary. It seems clear, however, that whichever of the above effects is concerned, the danger of injury occurs mainly when images of great concentrated brightness are formed on the retina of the eye.

There have been reports in newspapers of artistes suffering from eyesight troubles, which have been ascribed to the effect of exposure to very powerful illuminants. I have an extract from the *Picture Playgoers* (Nov. 22nd, 1919, p. 614) showing where several artistes of a film company are affected by semi-blindness, due, it is stated, to the powerful studio lights. The manifestation of this trouble in a severe form in this country seems to have coincided with the importation of certain types of lamps, though it may have existed in a minor form before then, due perhaps to carelessness in manipulation of arc lamps without suitable diffusers.

Dr. Chappe, in a paper read before the Société Française d'Ophtalmologie, said that "the painful results of the arc lamps' glare become most acute two or three hours after the artistes leave the studio." On his advice one studio has inaugurated a regular system of eye baths for artistes on the conclusion of the day's work. From an artistic and human point of view it is impossible for artistes to act naturally under the blinding glare of points of high intrinsic brilliancy. Producers are endeavouring to overcome the difficulty by providing coloured spectacles for artistes' use during rehearsals, and removing them before the actual "take." But how can one in these circumstances get the correct expressions? The human eye cannot instantly adapt itself to these great contrasts. One trade journal, *The Bioscope*, compares artistes with miners, as taking up a career of their own free will and fully cognisant of the risks they run. But, I may remark, up to a certain time the artistes were not aware of running any risks; also, that the miners are protected by Government regulations, and industrial factory operatives are similarly safeguarded.

Visual and Photographic Effect.

A point of very great importance in the lighting of kinema studios is the distinction between visible light and light of photographic value. The human eye is generally regarded as being sensitive to light within the wave-lengths of about $0{\cdot}39\mu$ (violet) to $0{\cdot}75\mu$ (deep red). The maximum luminosity occurs near $0{\cdot}55\mu$, corresponding to yellow-green coloured light, but the maximum chemical or photographic effect occurs near $0{\cdot}39\mu$, corresponding to the region just outside the visible rays. Thus for photographic purposes—that is, for actinic rays—the visual light is practically of no value as a guide. From the photographic standpoint, it is desirable, according to Dr. Mees of the Kodak Co., to select an illuminant with an abundance of rays of approximately $0{\cdot}40\mu$ wave-length, and a certain amount of ultra-violet rays. To attain this result efficiently one should dismiss the aim of producing an extravagant visual candle-power. Excess of ultra-violet rays has a prejudicial effect on the eyes, but it is known that all varieties of ultra-violet light are not equally injurious, and it would therefore be a useful inquiry to ascertain whether the rays which are chiefly needed from a photographic standpoint fall within the range of wave-length that is liable to cause eye trouble.

It is clearly of great importance to have available data comparing, not merely the efficiency of illuminants in a visual sense (i.e., for the purpose of creating *brightness*), but their relative value in terms of chemical or photographic effect. Dr. Mees remarks:—

> "For cinematograph work where halation is a difficulty it is an advantage therefore, both for the attaining of the best gradation and for the reduction of halation to a minimum, to use for these ordinary (photographic) materials, light of an average wave-length as near as possible $\lambda\,400\mu\mu$ rather than light having its maximum near $\lambda\,470\mu\mu$."

He gives the following data, applying to ordinary photographic work:—

*Photographic efficiency.**	
Enclosed arc as	62
Flame "	52
Mercury vapour (not quartz type; quartz is transparent to ultra-violet rays)	47

Constancy and steadiness of light.	
Arcs	Fair.
Mercury vapour	Good.

* Due regard must be paid to electrical current values when reading these figures.

Recently an impartial judge selected the best of a series of photographs taken by artificial light; this was produced by an illuminant using only ¾ of a unit of electricity per hour, as compared with others requiring respectively 3¼ and 6 units.

The Lighting of Scenes in Studios.

The qualities desirable in illuminants for use in kinema studies may be roughly summarised as follows: (*a*) high actinic value with relatively low consumption of energy and small losses in diffusion, reflection, and resistances; (*b*) low intrinsic brilliancy; (*c*) absence of heat or fumes or other harmful conditions; (*d*) long useful life; (*e*) constancy and steadiness of light. Some producers emphasise "snappiness," "needle-point sharpness," "crispness" as desirable qualities. Picture-goers, however, do not always comment favourably on these extreme black and white contrasts, which are fatiguing to the eyes.

At the present time one experiences the need of suitable instruments for testing photographic value—similar to those already available for the rapid determination of visible illumination. Present forms of actinometers which involve waiting for the coloration of a strip of sensitised paper are inconvenient and liable to present difficulties to an operator whose eye has already been fatigued by or dazzled by looking at the lights. I suggest the use of some convenient unit, such as photmen or phot, similar to the term "lumen," which is used for visual illumination and which is readily ascertained by simple devices.

In the studio methods of directing and occasionally shading the light deserve study. The suggestion that illuminants using white light should be covered with blue glass cannot be approved. In this way the actinic value for a given visible illumination would doubtless be increased, and possibly the device might tend towards the comfort of actors. But such screening involves a loss in efficiency. One merely absorbs a considerable amount of visible light and some ultra-violet. What is desirable is to produce a source which itself emits radiation of the requisite quality, bearing in mind that, at the present time, certain difficulties are experienced with a film base of a panchromatic nature.

---

REPORT ON THE GLOVER SERUM.

AN interim report has been presented by the special committee appointed by the council of the Academy of Medicine, Toronto, to examine all the available data, experimental and clinical, upon which Dr. Glover had based his claims to advance our knowledge of the causation and treatment of cancer. The data which the committee was able to obtain did not convince it that the results of treatment by the use of Dr. Glover's serum were better than those obtained by similar methods introduced by others, which had ultimately disappointed the hopes entertained of them. The report is signed by W. H. Harris (chairman), H. B. Anderson, Herbert A. Bruce, John J. MacKenzie, Jabez H. Elliott (ex-officio), Harris McPhedran (secretary), and received the concurrence of Geoffrey Boyd, W. P. Caven, and A. Primrose, who were added to the committee. It was adopted by the council of the Academy on Jan. 13th.

A CHILD PILGRIMAGE LASTING TWO YEARS.

WE have received from *La Nouvelle Revue* (Paris) a brochure entitled "800 Enfants Russes autour du Monde," in which Mons. P.-L. Hervier sets out attractively the adventures of the 800 Russian children, the residue of a much larger number of children of well-to-do Petrograd parents, who sent them to the Ural in the spring of 1918 on the assurance of safety and plenty there. Cut off in the summer by the varying fortune in the encounter between Czecho-Slovak troops and the Red army, and deserted by many of their supervisors, these children began to run wild in the woods, seeking their own food. In January, 1919, the American Red Cross took them in charge and conducted them by easy stages round the world—Vladivostok, San Francisco, Panama Canal, New York, Finland—back again to Petrograd at the end of 1920, where a committee of parents was prepared to receive them. At New York the children showed their initiative by refusing to go to a camp being prepared for them near Bordeaux, electing to go straight home whatever might be the privations in store for them.

"IRIDIAGNOSIS."

ANY claim to a startling discovery by a layman in the domain of medicine is certain of a wide advertisement irrespective of its inherent credibility. A few weeks ago we commented on the claim of a Paris professor to have discovered hitherto unknown organs of vision, enabling the blind to see. Now we are told that a graduate of Edinburgh University has been lecturing in London on a new method of diagnosing all sorts of diseases merely by gazing into the eyes of the sufferer. It seems that the condition of every organ and part of the body is reflected in the iris. By this means, an interviewer for the *Star* was told, it is possible to diagnose not only the ailments from which anyone may be suffering, but also the remedies which have been adopted to treat them. Nothing, apparently, eludes the "peering, incisive look" of the "iridiagnostician," whether it is a cured cold, the quinine that has been taken to cure the cold, a cut finger which has healed, or even incipient cancer.

It is, we think, an unfortunate fact that to the majority of people the human body is as mysterious a subject as is the human mind to nearly all of us. Perhaps to include a little elementary physiology in ordinary school teaching would be the best antidote to the rubbish on the subject which finds its way to popular notice. Meantime, we are not surprised that the possibilities of the iris in this connexion have been exploited. The iris is one of the most variable, as it is one of the most beautiful structures in the human body. The distribution of pigment in it is not, any more than the conformation of the cutaneous ridges on the fingers, identical in any two individuals. Unfortunately for the theory put forward, the pigmentation of the iris is laid down once for all in early life, and, save as the result of diseases directly affecting the eye itself, does not change in later years. With this exception, therefore, the only problems on which the pigmentation of the iris can throw any light are those connected with heredity.

COLONIAL HEALTH REPORTS.

Nyasaland.—In the report for 1918-19 the following reference to the public health occurs: "Owing to the presence during 1918 of the German enemy forces along the eastern borders of Nyasaland and on Lake Nyasa there was a widespread and continuous movement of our troops, followers, and carriers within the Protectorate throughout the year, movements which afforded every facility for the spread of infectious and contagious diseases. Small-pox was confined to the districts in which it was prevalent in the previous year, though sporadic outbreaks occurred in other areas, but with the assistance of the military medical officers these outbreaks were promptly dealt with and did not assume an epidemic intensity. There were only five cases of bubonic plague reported from the North Nyasa district in the neighbourhood of Karonga, as against 25 in the previous year and 15 in the year before that. No recurrence of cerebro-spinal fever occurred during the year, and this disease may now be regarded as non-existent in Nyasaland. From the epidemiological point of view one of the most notable events of the year, and a factor affecting the public health of the Protectorate more prejudicially than any other, was the appearance of influenza in the month of November. This epidemic rapidly spread throughout the Protectorate, reached its maximum intensity in December, and declined steadily during the month of January. The number of Europeans resident in the Protectorate on March 31st, 1919, including officials, was 492 males and 232 females, as compared with 463 males and 252 females in the previous year. The Asiatic population numbered 407. The native population is estimated at 1,216,100—approximately 551,600 males and 664,000 females.

Turks and Caicos Islands.—Mr. G. Whitfield Smith, the commissioner and acting judge for these West India Islands (geographically forming a sort of annexe of the Bahama group), writes in his report for 1919: "No serious epidemic or outbreak of sickness was reported during the year. The number of births was 173 and of deaths 169, representing 30·8 and 30 per 1000 of the population respectively. On Jan. 9th 64 natives of the Dependency perished at the stranding of the s.s. *Yuna* on Mouchoir Bank, which accounts for the abnormally high death-rate. The Manning Hospital continues to minister to the needs of suffering humanity in a most satisfactory manner; 55 cases are stated by Dr. H. H. Purinton to have received treatment at this hospital during the quarter ending Sept. 30th, 1919, and the acting Government Medical Officer concludes his report by saying there are few, if any, public expenditures in the Island of Grand Turk, and, in fact, in the whole Colony, which have been a greater benefit to the population than the money spent for the support of the Manning Hospital."

"SQUINT, MANCINISM, AND TUBERCLE."

To the Editor of THE LANCET.

SIR,—"Squint" being a vernacular word, and lay journalists being in the habit of looking at THE LANCET, it results that the article in your last week's issue got into a daily paper, unfortunately with mention of my name, after which an interviewer called and was refused what he asked. Publication of this disclaimer would oblige.

I am, Sir, yours faithfully,
THE AUTHOR.
Feb. 13th, 1921.

To the Editor of THE LANCET.

SIR,—Dr. Rivers in his interesting article upon squint in this week's LANCET uses the term "mancinism" as indicating left-handedness. I cannot find this word in any dictionary, lay or medical. For the benefit of those who may be as ignorant as myself, will Dr. Rivers kindly give its etymology?

I am, Sir, yours faithfully,
IGNORAMUS.
Feb. 13th, 1921.

⁂ If "Ignoramus" consults the "Dictionary of Medicine" (Gould) he will see that it simply gives the following entry: "Mancinism (*mancus*, imperfect, maimed), left-handedness." This probably is based on the statement of Ulpian, the Roman jurist, who refers to two kinds of left-handed persons, he that is naturally left-handed being called "scæva" and he that uses the left hand through a weakness of the right being called "mancus." This word seems to have been borrowed by the French in the word "manchot," and to have meant that through a weakness in either hand the other was used only, as displayed in the couplet by Delille (1738-1813), a French classical poet, who occupied the chair of Latin poetry at the Collège de France:—

> "Le bras manchot qui, resté sans office,
> Laisse au survivancier tout le poids du service,"

the word "survivancier" being "reversioner" in English. Now the word "manchot" seems to be more applied to a one-handed or one-armed person (à qui il manque un bras ou une main).—ED. L.

THE LANCET, FEBRUARY 26, 1921.

An Address

ON

INTERNATIONAL ORGANISATION AND PUBLIC HEALTH.

Read before the Society of Medical Officers of Health on Feb. 18th, 1921,

BY G. S. BUCHANAN, C.B., M.D. LOND.,
SENIOR MEDICAL OFFICER, MINISTRY OF HEALTH.

THE invitation of your President gives me the opportunity of drawing the attention of the society to some recent international arrangements for the promotion of public health, and in particular I have thought it would be of interest to say a few words about the International Health Organisation which will shortly come into being, as a result of a series of detailed resolutions which were passed by the Assembly of the League of Nations at Geneva in December. With the project envisaged by these resolutions I have personally been somewhat closely associated, as it was my privilege to be nominated by the Ministry of Health, on the recommendation of the chief medical officer, to be the technical adviser on this subject to the British delegation, and, what in this connexion was perhaps more important, to take part in the original international discussions which were initiated by Dr. Addison more than a year ago, when it became necessary to examine the position in regard to international health matters which had been created by the Treaty of Versailles.

THE LEAGUE OF NATIONS AND PUBLIC HEALTH.

It will be remembered that by the Covenant of the League of Nations, which forms an integral part of that Treaty, the members of the League undertake to take steps in matters of international concern for the prevention and control of disease. The League is also empowered to take over the direction of international bureaux established by general treaties, among which is included the existing Office International d'Hygiène Publique, which was established by the Convention of Rome, 1907.

These provisions undoubtedly form something of a land-mark in public health history by giving formal expression to the importance which health questions now assume in the practical affairs of the government of the nations of the world. They show, internationally, the effect of the same movements which in this country led to the central amalgamation of health services and the creation of a Minister of Health; which in France also have since led to the splitting off of public health administration from the other departmental matters which were overshadowing it at the Ministry of the Interior; which have resulted in the Ministries of Health which have been established in the new countries of Central Europe; and which have brought about also the remodelling and strengthening of central public health services which we are now witnessing in the United States and in our own Dominions. The Covenant wisely recognised that as nations thus increase and strengthen their internal health government, new points of contact, need for common action, and even risks of political differences must arise internationally. It was necessary that a league designed to secure comity among nations, and to prevent or resolve disputes, should bring public health questions within its range of activities.

The practical sanitarian, accustomed to look with small enthusiasm on the elaboration of schemes which appear far reaching only on paper, and with that mistrust of long views which is so useful in the pursuit of our calling, is perhaps likely to exhibit only a mild interest in the fact that the League of Nations, whose own future in many directions is uncertain, has taken to itself a wide outlook over technical matters—economics, finance, international transit, world conditions of labour, and the like—and has added public health to them. It is for him of greater interest to take the short view, and to ask first whether, as a practical matter, international official action can contribute anything worth having at the present time to public health that cannot be obtained as easily without it and then to inquire how, through the League of Nations or otherwise, *it is proposed that this action should be taken.* The manner of doing things, as he knows well, is often as least as important as the matter of them.

LIMITATIONS OF OFFICIAL INTERNATIONAL WORK.

To answer this question it may be useful to begin, and perhaps rather in a wholesale way, by a process of elimination. It must be remembered that the League of Nations represents associated Governments, and its activities depend first and last on the views and action of Governments, in other words, it is an official machinery if it is anything. For international cöoperation in health questions that do not require official or Government intervention and support a League of Nations machinery would offer little advantage. Accepting this, we can at once exclude from the question before us much that can in a general sense be termed international medical work. All medical science, in a sense, is international; it is as cosmopolitan as music. In medicine, least of all, do we want to ask, when we hear news of progress, whether or not it is "official." Jenner, Pasteur, Metchnikoff, Ehrlich—it is the man's work that leaps to the mind with names such as these, *not their nationality.* We do not need to set up an international bureau to tell us in all the official languages of discoveries and new knowledge given us by workers all over the world. Have we not enough—even more than enough—of abstracts and summaries and translations? There are special cases, to which I will refer shortly, where we can only get the information we require for public health work through Governments, but all will agree that our own journals, not forgetting the "Medical Science Abstracts and Reviews" of the Medical Research Council, which give them freely and in one tongue, amply suffice for all ordinary needs, while we have also all our medical societies—always on the look-out for information from other countries—and our international medical and sanitary congresses which are all the better for their voluntary character and independence.

International Medical Research.

So also with research. At the Assembly at Geneva much attention was given to an attractive proposal by the Argentine delegates that the League of Nations should promote medical research on a large scale by establishing and financing a large central research institution, and should take active part in the establishment of health laboratories all over the world for the investigation and prevention of disease. The project, had it been pressed and accepted in committee, would probably have been wrecked on the financial rocks; the budget and commitments of the League and its proposed technical organisations were being closely scrutinised. But it was at least debatable whether on its merits it would have been right to press it. Someone once proposed to give a great mansion and grounds for habitation by poets, where their products could be turned out under ideal conditions of comfort and in contact with other poetic minds. The true medical research worker would probably be as horrified at the prospect as the poet. Without shutting the door to future functions of an official international health office as a clearing-house for certain kinds of research work—a matter obviously to be considered—it cannot be maintained that nations wishing to progress in medical science would be doing their best by putting their men and money into any international forcing house for research. Both would be better employed at home. Moreover, the days of private support to public medicine are happily not over. The Rockefeller Foundation, with its world-wide humanitarian scope, gives us an example of a magnificent form of internationalism all the more effective by its freedom from official control.

International Red Cross Activities.

So again with the great humanitarian institutions. The benevolent in all civilised countries combined in

No. 5087.

the interests of international public health. The various Red Cross organisations, now so much strengthened in authority and funds by the war, have united to form a common organisation—the League of Red Cross Societies—which is to work for health in time of peace, with the special function of educating and helping backward or poverty-stricken countries. These Red Cross activities received special recognition in the Covenant of the League of Nations, which requires the signatory countries to encourage them. I do not propose here to formulate the lines of demarkation which should be followed between this important voluntary body and an official health organisation of the League of Nations, especially as the matter has been recently and fully discussed by Sir G. Newman in his first annual report to the Ministry of Health. The various conferences on the subject have always led to the same conclusion—namely, that in practice the line should be easily drawn (the more so as the League of Red Cross Societies is itself established in Geneva); that not only should there be no reason for rivalry, but each should be strengthened by the other. It is the fact, I believe, that the League of Red Cross Societies has already found itself hampered by the absence of a health section at the League of Nations, and it is obvious that the latter, when established, will be much advantaged by what has already been accomplished and prepared by the Red Cross organisation. The situation, in fact, is one which is familiar to public health officers in every administrative area where voluntary work and expenditure of voluntary funds on health matters go on side by side with official work, and when ordinary tact and prudence are exercised harmony and mutual benefit are secured.

OBJECTS OF THE INTERNATIONAL HEALTH ORGANISATION OF THE LEAGUE.

If any further fears are entertained that those who have been concerned with this question have been carried away by unreasoning international idealism, or have bureaucratic designs to capture public medicine at large by some new international machinery, they will, I think, be sufficiently dispelled by a study of the objects which the proposed organisation is in fact required to fulfil. These objects are stated as follows in the resolutions of the Assembly; it will be seen that their terms are carefully guarded.

(*a*) To advise the League of Nations in matters affecting health.

(*b*) To bring administrative health authorities in different countries into closer relationship with each other.

(*c*) To organise means of more rapid interchange of information on matters where immediate precautions against disease may be required (e.g., epidemics) and to simplify methods for acting rapidly on such information where it affects more than one country.

(*d*) To furnish a ready organisation for securing or revising necessary international agreements for administrative action in matters of health, and more particularly for examining those subjects which it is proposed to bring before the Standing and General Committees, with a view to international conventions.

(*e*) In regard to measures for the protection of the worker against sickness, disease and injury arising out of his employment, which fall within the province of the International Labour Organisation, the International Health Organisation will coöperate with and assist the International Labour Organisation, it being understood that the International Labour Organisation will on its side act in consultation with the International Health Organisation in regard to all health matters.

(*f*) To confer and coöperate with international Red Cross societies and other similar societies under Article 25 of the Covenant.

(*g*) To advise, when requested, other voluntary organisations in health matters of international concern.

(*h*) To organise missions in connexion with matters of health at the request of the League of Nations and with the concurrence of the countries affected within the limits provided by Sub-paragraph (*a*) or by the International Convention of Rome (1907).

SOME QUESTIONS AWAITING INTERNATIONAL AGREEMENTS.

The way is now clearer to continue with the practical question which I have assumed to be put. The objects of the organisation have been settled and defined in the general terms which I have just read. Representatives of the public health departments of the civilised countries of the world will be collected together to pursue them. What is ready to their hand to begin upon? The material is really abundant, and none the less important because the subjects concerned are somewhat technical and unlikely to make much appeal to popular imagination.

New International Sanitary Conventions.

Let me illustrate this first by health questions connected with sea and land frontiers. The measures taken in regard to ships coming from infected ports have in this country a long history beginning with the now obsolete Quarantine Acts, going on to the International Sanitary Convention of 1903, with which our present practice conforms, and ending with the most recent International Sanitary Convention, that of 1912, the ratification of which was completed only a few months ago. One of the most creditable contributions of this country to the public health of the world resulted from the appreciation which was given in England at a very early stage to the fundamental principles which should govern the action taken by port authorities to prevent the introduction of diseases like cholera and plague, so as to combine a maximum of efficiency with a minimum of interference with traffic and commerce. The international adoption of these principles, though secured by international agreements, has, however, not seldom stopped at the signature of these agreements. Some countries have regarded sanitary conventions as merely giving minimum requirements, and in practice have superseded them by laws and regulations greatly in excess of the principles of the agreements to which they are signatory. Other countries, including certain of the British colonies, have stayed out of the Conventions and retained old-fashioned quarantine laws. All these Conventions depend in large measure on a system of formal notification to other countries of the first occurrence of plague or cholera in an affected country, but their requirement has often been defeated by the burden of its own formality. Under the Conventions the health department of one country does not notify the health department of another, but the information proceeds through diplomatic channels and Foreign Offices, for which, naturally enough, any report of plague or cholera carries with it visions of disaster, restrictions, reprisals, and other fantasies which attend the unknown, and thus leads, if not to suppression of facts, at least to delay and to studied ambiguity in their presentment which defeats the object of the notification. And perhaps the greatest difficulty with these Conventions—the observance of which is of such great importance to commerce as well as to health—is their absence of elasticity. The Convention of 1912, drawn up after long conferences and discussions, was ratified only last year. Though in many ways a satisfactory code and in advance of that of 1903, it is already in several respects out of date. In regard to plague precautions on ships it still treats human plague infection and not rat plague infection as the primary consideration; in regard to cholera, it gives no sufficient guide about the carrier; in regard to yellow fever, its requirements do not satisfy, and are not practised by, any of the countries in the yellow fever zone, and they are considered insufficient by India, which is now apprehensive of the introduction of this disease.

Meanwhile, there is an insistent demand, not only from our own administration, but from that of many other nations, for the establishment of international rules which should govern the handling of other infections, such as small-pox and typhus, not dealt with in the present Conventions. These are of daily importance, particularly in connexion with the migrations which are beginning, and likely to be continued, from the epidemic-stricken regions of Eastern Europe. The demand for revision here extends to the case of land frontiers, which hitherto have received scant consideration in international conventions. The division of large parts of Europe into new States, the probability that for many years to come small-pox, typhus, cholera, and other acute epidemics may progress westward through the Continent, and particularly the unhappy experience already gained on the borders of Poland and Soviet Russia, make it essential on land frontiers that, on the one hand, strict measures should be taken for observation, detention, disinfection, and the like, applicable to persons of all nationalities, and on the other hand, that these measures, like those for shipping, should be so contrived as to produce the minimum of interference and annoyance in international traffic and commerce.

Now, in present circumstances, it is difficult for any busy public health officer to contemplate without dismay the prospect of a new and protracted official international conference to recast and reconsider all these questions in detail. Many new States will, for the first time, come into these deliberations; they cover a larger ground than before; and when a solution is ultimately arrived at there is a prospect that it can only be made effective by a repetition of the diplomatic procedure which delayed us for eight years after 1912; that the resulting document might once again be out of date by the time it is ratified; and that it would after all leave us as uncertain as before of the extent to which the Convention, when completed, was observed in practice by the signatory countries.

An official central health bureau, with international authority and adequate machinery, affords the most hopeful way out. It has already been proposed that the next International Sanitary Convention should be framed on broader and simpler lines, leaving details to be filled in by schedules and supplementary agreements. This is feasible if a standing expert authority has the duty of making adjustments as occasion requires to meet advances in knowledge and changes in the epidemic situation. In an International Health Organisation on which all the central health departments of the chief maritime States are represented, there should be no difficulty in designating the right men for this purpose and in securing international approval of necessary amendments without long delays and needless formalities. Such an organisation, moreover, could do much to secure that accurate information is obtained regarding the measures taken in each country to give effect to the agreements. The Geneva Resolutions, besides providing for this central body, lay down a new method for the conclusion of Conventions on health matters which, it may be hoped, will remove some of the obstacles met with hitherto. The efficacy of this method has still to be tested, but in any case the main cause of past delays, the fact that it has been nobody's business to see to progress, should now be removed.

Epidemic Intelligence.

Another matter requiring attention at the present time is the collection of intelligence regarding the progress and prevalence of principal epidemic diseases. At the Ministry of Health we find this essential not only for our own sanitary administration but also to meet, as we desire to do, the strongly expressed wishes of our self-governing Dominions for such systematic intelligence. Port medical officers of health who receive from the Ministry the weekly statements of epidemic diseases abroad, which have lately been much expanded and improved through the energy of my colleague Colonel S. P. James, will realise the duplications of labour which result from the present system; indeed its absurdity when it is remembered that other countries, like the United States, are laboriously and independently following the same method. At present we obtain a large amount of our information about epidemics by the coöperation of our Foreign Office and through the zeal of British consuls abroad. In existing conditions this is the only way, and is most helpful. But, after all, the consul, himself a layman, has to approach a foreign lay municipality for his facts, and at best can obtain them only for a limited area of the country. Other consuls at the same place are going through the same system of inquiry and cabling to their Governments. For some countries —China, for instance—no efficient substitute for consular information can be suggested. But for many nations it ought to be practicable to replace messages from British representatives in a few centres by a single communication sent to the Ministry of Health by the corresponding department of the foreign country. We are already in England able to give such information either to other countries or to a central office. The practicability of the establishment of a central epidemic intelligence centre in connexion with the new International Health Organisation needs to be studied in detail and as soon as possible. It would hasten more than any other measure the codification of epidemic intelligence in countries, like France, which have not yet developed notification as we know it over here. Given the necessary communications from the periphery, a central transmitting station such as the League of Nations is bound to possess, and the condensing resources of a code, it should not be difficult in a few words to signify each week to all the countries the main facts of each of the principal epidemics which require to be watched. Much less useful matter is daily transmitted all over the world by wireless. The expense should not be great and would be saved in other directions by every country concerned.

Health of Ships' Crews.

The hygiene of ships, so far as it affects that deserving but often hygienically neglected section of the population termed merchant seamen, is receiving attention on the international side from the International Labour Office, and is being brought into great prominence by seamen's labour organisations all over the world. Its settlement requires international action in which the best and most recent public health knowledge should be incorporated. The Geneva Resolutions establishing the International Health Organisation have now provided a means by which competent sanitarians can take their proper part in the international regulation of matters like ship ventilation, the construction of crews' quarters, their rations, facilities for cleansing, and the like. The subject bristles with difficulties, but also with great opportunities, and I may express the hope that when proposals on this matter are taking concrete form the British delegates may have the advantage of assistance from those medical officers of health of port sanitary authorities who have specially studied the hygiene of ships' crews.

Let me refer also to another international measure affecting merchant seamen—their treatment for venereal disease at seaports. This ground has been explored officially by the Ministry of Health, and unofficially by the National Council for Combating Venereal Diseases, and it is clear that international agreement is both desirable and practical to ensure that at any large seaport the sailor has access to modern methods of treatment, without charge or disability to himself, without reference to his nationality, and, if I may express a personal view, without cost or prejudice to the shipowner. This treatment should include in-patient treatment where necessary, and a standard form of record of his condition and treatment—forms of record really may have their uses—which he can take with him to the next port. Nothing approaching this system at present exists, but little consideration is necessary to realise the gain which might accrue from such an international undertaking. The practical difficulty hitherto has been that no one nation has been in position to press the matter strongly on other nations and remove the minor obstacles, still less to secure that the goodwill and assent of other countries, when obtained, is translated into appropriate action.

Anthrax: Rat Destruction.

I may refer to two or three other health questions which seem ripe for international agreement or study with a view to agreement, and where necessary should be taken up in consultation with the International Labour Office in the interest of the workers. One is anthrax, where at least two things are required: first, the general adoption of a system officially recognising that raw hides and wool have been disinfected by an approved process at the place of their collection or the port of despatch. This system, which would produce a great saving and greater efficiency, has been shown to be practicable by the work of Dr. T. M. Legge, Dr. F. W.

Eurich, and others in this country, and the minute attention given to the whole question by the Anthrax Committee and the Home Office. Secondly, there is real need for an understanding about the future of the important Japanese export trade in shaving brushes. As you are aware, the British Government has been obliged by the demonstrated danger of these brushes to prohibit their importation altogether. It is undesirable that we should have been forced to this procedure, especially as other countries have not taken corresponding action. The real remedy seems to lie in action in Japan to secure that the hair, usually imported from China, is efficiently cleansed and disinfected before it is made up, under supervision by Japanese bacteriologists in whom all the world can have confidence, officially arranged and guaranteed by the Japanese Government.

Then again, to revert to a subject which affects port sanitary authorities and shipping, is the subject of periodic destruction of rats on ships. There is no reason why a ship should not be overhauled to remove its rats every six months as a routine just as necessary as its repainting, or the overhaul of its boilers. Such a requirement, which would be greatly in the interests of shipowners as well as of health, could only be effected by international agreement, coupled with a system of intelligence at the central offices regarding the action to give effect to the requirements of that agreement.

International Vital Statistics.

There can be no doubt that the work of medical statisticians is greatly hampered by unnecessary differences which at present exist in methods of certifying and of recording deaths. I may draw attention in this connexion to a useful article on death certification contributed by Professor J. Glaister to the last number of the *Journal of Comparative Legislation.* When one remembers that the vital statistics of Switzerland, for example, are obtained by a system of confidential certification in which the medical cause of death is not stated to friends and relatives, one realises how large a discrepancy there may be in the comparison of the vital statistics of that country with others in respect, let us say, of alcoholism or syphilis. Then, again, the use by the certifying doctor of "primary" and "secondary" causes of death is a matter in which there are divergences so wide as to make vital statistics which are seemingly comparable really incompatible in actual fact. Even as between England and Scotland, as you are aware, there are a few differences of this kind—a death which is certified as due primarily to influenza and secondarily to pneumonia, will in England be ascribed to influenza and in Scotland to pneumonia. There must, of course, be substantial differences between countries in regard to the reliability of their death certificates and vital statistics, even between those which are most highly civilised; but at the same time a great many points of difference have only to be pointed out and discussed in order to be removed, with great advantage to comparative work. Some effective progress has already been made in this matter on the question of tabulation of causes of death under the headings of the International List, which is revised every 10 years. The Conference last year at Paris, which completed the most recent decennial revision, was at once an example of the praiseworthy desire of statisticians and registrars to obtain international accord in their "long" and "short" lists of cases of death, and a demonstration of the ineffectiveness of the arrangements which at present exist to bring about that accord in a satisfactory and convenient manner. Anyone who experienced, as I did, the difficulties of discussion of a large number of complicated details by 50 delegates of different nations, meeting on four consecutive days from early morning to late night, and trying to make progress without agreed rules of procedure, agenda, drafts, copyists, shorthand-writers, or interpreters, would not need to be convinced of the practical advantage of transferring such work to a centre where all these arrangements for international discussion are automatically and well supplied.

Exceptional Epidemic Conditions: the Typhus Commission.

Another important aspect of international official work lies in the direction of combining efforts to deal with exceptional epidemic conditions. This has already been illustrated in connexion with the advance of typhus and cholera from Russia into Eastern Europe. To check that advance, especially by dealing at the frontiers with the large numbers of refugees, prisoners of war, and the like, arriving from the East in mass along the principal railway lines, en route to all parts of Europe, is a matter which obviously concerns many Governments very vitally, apart altogether from the humanitarian aspect of the question, which may be considered to affect the whole world. A large amount of voluntary aid has been forthcoming or promised to deal with this situation, especially through the Red Cross agencies, but the conditions in Poland and the other border States has been such that it has been impossible for this voluntary action to be made effective without strong official international backing. Moreover, the resources of the charitable public in the United States and elsewhere have been insufficient to secure the necessary preventive measures on a sufficient and systematic scale. In these circumstances the League of Nations, as is well known, has made an effort to supply the need by appointing a special epidemic commission and obtaining funds for this work from a large number of the Governments represented in the League. Although these funds are not yet adequate for the purpose, they have even now been sufficient to enable a good start to be made in the most difficult and dangerous area, and the Typhus Commission, with general consent, is now able to attach to itself, or direct the use of, the important auxiliary services which the Red Cross bodies are able to bring in.

Occurrences of this kind are not likely to be numerous, as in all ordinary cases an epidemic-stricken country would take its own measures and be unwilling to call for, or to receive, international official help. When they do occur, however, as to-day in Eastern Europe, or as they may arise to-morrow, say, in the case of pneumonic plague in the East, it is evident that the League of Nations can only act effectively and quickly if it has behind it experts who can appreciate the situation and the needs of the case, and are in close touch with their Governments. The absence of a public health organisation in the present case has been one of the serious handicaps to the League in the prosecution of its campaign against typhus. It may be added that if the Treaty of Sèvres is ratified, still more if it is taken as a precedent for other treaties, the League of Nations will assume a very direct responsibility in regard to quarantine. Under that Treaty the League will be required to form a special committee to coördinate the practice of the different quarantine stations which deal with the Mecca pilgrimage.

THE MACHINERY OF THE INTERNATIONAL HEALTH ORGANISATION.

Leaving these questions of the work before the organisation, we may now consider the further practical question how such work is to be effected. It requires that a body of men should be got together at least once or twice a year from a large number of countries who are persons of some weight and authority in the public health work of their respective Governments and who, if they are not themselves expert in the particular technical question of the moment, will have been able to obtain or to bring the best technical assistance or advice on the subject. If we were on entirely new ground with no experience, it might be difficult to say that this is likely to be practicable. Fortunately, however, we have the necessary experience. Such meetings to a large extent already take place once if not twice a year at the Committee of the Office International d'Hygiène Publique in Paris, which is to form an integral part of the new organisation. This Committee is in one important respect wider than any body could be which only represents members of the League of Nations at the present time, as it includes the representative of the United States Public Health Service.

The Office International d'Hygiène Publique was established by the Convention of Rome of 1907 with a constitution which enables it, as a consultative body, to deal with most, if not all, of the subjects which I have mentioned above. The value of the past work of the Office International must not be belittled or overlooked. It is hardly as well known in this country as it should be. The Office has been a very bad advertiser, and, as its meeting place and offices are in Paris and its official language is French, it has been regarded here as perhaps too exclusively a Latin institution. The *procès verbaux* of its meetings are formidable official records which are seldom found outside Government offices, and its Monthly Bulletin—which is on sale, and incidentally, at the rate of exchange of to-day, represents a higher public health value than any other periodical known to me that is purchasable for *5d.*—is largely concerned with official regulations, and its epidemic intelligence and excellent abstracts are apt to be a little out of date.

As regards its conferences, I can only speak personally regarding those held since the armistice under the able presidency of Monsieur Velghe, the principal officer of the Belgian Public Health Service. There can be no question of the great practical value of these meetings, which has been proved, especially in connexion with the information interchanged and collected regarding the influenza pandemic, the present prevalence of encephalitis lethargica, the practical measures adopted to deal with venereal disease in different countries, and other matters. At the recent sessions, moreover, since the question was raised of providing for international health work on a larger scale and with more important machinery and larger funds, the delegates to the Office International have most materially advanced the consideration of a number of international questions to which I have already alluded, in particular the revision of the sanitary conventions and the proposed agreement to deal with venereal disease at seaports. In general it may be said that the delegates are precisely the men who would be selected by their Governments to represent them on any important international health question involving official action. The British Empire representation has recently been a strong one, as we have been fortunate in including representatives who are either leading public health officers in their respective British countries or have recently held such appointments.

Continuance and Incorporation of the Office International d'Hygiène Publique.

All those who have had to consider the way in which the health obligations in the League of Nations Covenant should be met and the nature of the problems before us have agreed that continuity should be secured and that the League would benefit by the experience and personnel of the Office International. Moreover, the Covenant has made it impossible for the Office International to develop in any useful direction by continuing an independent existence. This view by general consent and goodwill has now been adopted in the resolutions of the Assembly. The International Health Organisation is to be based on the Office International, which will in future have additional representatives from certain countries, like Japan, which are members of the League, but have not previously sent delegates to the Office. The League of Nations system of General Assembly, Council, and Secretariat has, broadly speaking, been followed in the subsequent arrangements. The Committee of the Office International, enlarged as indicated, becomes the equivalent of the General Assembly of all the nations. In the capacity of the General Committee of the International Health Organisation, it will continue to meet in Paris once or twice a year and retain its offices there. Its work will be carried on under its former constitution with such modifications as may be necessary to fulfil its further duties of advising the League. It will, however, be provided with a Standing Committee, roughly analogous to the Council of the League, which can meet in the intervals of the general meetings, appoint subcommittees and arrange for export inquiries; and it is to have a medical secretary and International Health Bureau at Geneva. The Assembly has allotted some £17,000 to the organisation for its first year, and it will continue to receive also the relatively small contributions from the signatory Governments which have hitherto supported the Office International.

Central Bureaucracy.

It may be noted with satisfaction that the official requirements for the working of the organisation laid down by the resolutions of the Assembly are, as international arrangements go, relatively simple. Much latitude has been given to the organisation to work out its own procedure as circumstances dictate. It is true that the system could have been very considerably simplified if we could have envisaged the appointment at Geneva of a superman for international health, possessing a large central office and staff, in position to prosecute inquiries in and demand information from the respective national health offices of the world, and to lay down international rules with which those national offices would comply. But no public health department in any country would be prepared to accept this dictation at the hands of any man, however distinguished. And if they were so prepared, no Government would be disposed to accept such a system. There were, indeed, many indications at Geneva of the intrinsic objection held by the representatives of the constituent nations of the League to any international procedure which suggested servitude to a central bureaucracy.

Common action among nations (for purposes such as we are considering) must depend upon the fullest discussion and consideration of the position of each country—even in such technical matters as quarantine laws, or death certification, or standards of ships' hygiene—and on willing agreement after such discussion. This means a slow rate of progress, of course, but it is necessary, and the originators of the health scheme have recognised it by making the meetings of representatives of all countries—i.e., the General Committee which continues the Office International d'Hygiène Publique—the real basis of the organisation: the new additions of standing committees and secretariat being the necessary auxiliaries to its efficient work. Any permanent headquarter officers who are appointed will need ability and experience in handling the subjects for inquiry and giving effect to the decision of the international representative body. But these after all are qualities exercised every day by medical officers in every important public health service, no more difficult or complicated than managing the health matters of a great municipality. They require good men, but not Napoleons.

THE OPPORTUNITY OF STATE PUBLIC HEALTH DEPARTMENTS.

It is permissible, I think, to conclude from this short survey that the International Health Organisation of the League of Nations will have before it on its formation a number of important practical matters of hygiene which are ripe for concerted government action, and call for an organised action by the official public health services of the civilised Governments of the world; that it will start on these subjects with the advantage of continuing the collaboration which has been obtained in the more limited sphere of the Office International d'Hygiène Publique under the Rome Convention of 1907, and of the preliminary work already done by that Office in several of the subjects awaiting settlement; and, finally, that the means and funds placed at the disposal of the organisation for meetings, inquiries, and draft agreements, promise to be satisfactory for the purpose.

I think this is quite enough to enable us to wish it a good start and every success on an admittedly difficult road, without prophesying for it a future extension in many other directions which can be suggested, or must even be anticipated, if the League of Nations increases its authority and influence, or if, whether through the League of Nations or in any other way, the countries of the world demand in future a much closer degree of international coöperation for objects such as public health. In any event the outlook for the organisation will largely depend on the willingness of the public health services in the different countries to make use of the present opportunity, and the support which these services in so doing receive from their Governments. One satisfactory part of the scheme adopted by the Assembly should be noted. The League of Nations will have its budget control, a certain power of withholding sanction to action proposed by the organisation, the right of sanctioning appointments of paid officers and of receiving reports, but, apart from these, the general working of the organisation, the regulation of its internal affairs, and the appointment of staff is left entirely to the organisation itself—in other words, to the public health men themselves.

Here is the opportunity of the public health officers, and it is to be hoped that they will not only be willing to seize it—this may be taken for granted—but will find themselves in position to give necessary time and labour to ensure its success, and be supported in their respective countries by departments which realise that practical international action and agreement is a fundamental part of any good State public health policy. As regards countries within or associated with the British Empire we have every reason to anticipate that this support will be given, in the Dominions, India and Egypt, as well as at home.

As I have said so much about this new organisation, it is only fitting that I should conclude by reference to a few of those to whom the fact that it has now been established by resolution of the Assembly is mainly due. These preliminary steps have not been achieved without labour. Many of us have worked hard at the matter at the Ministry of Health, and much is due to our French colleagues, Mons. Brisac and Dr. Léon Bernard, to Dr. Lutrario (the chief of the public health service in Italy), to Dr. Hugh Cumming (now head of the United States Public Health Service), to the Japanese representation, and especially to the principal officers of the secretariat of the League of Nations and of the Office International d'Hygiène Publique—all of whom originally took part in working out the main lines in 1919 at the London Conference under the guidance of Lord Astor. At the Assembly itself the scheme was fortunate in having such able exponents as the Rt. Hon. G. L. Barnes, M.P., one of the delegates for Great Britain, and Mons. Gabriel Hanotaux for France; their statesmanship and industry piloted it past the not inconsiderable difficulties inherent in the first establishment of international technical organisations by the League, and in the official requirement that resolutions of the Assembly can only be obtained by a unanimous vote of all the nations represented.

THE CEREBRO-SPINAL FLUID IN DISSEMINATED SCLEROSIS.

BY DOUGLAS KINCHIN ADAMS, M.A., B.Sc., M.B.,
CH.B. GLASG., F.R.F.P.S. GLASG.,

ASSISTANT TO REGIUS PROFESSOR OF MEDICINE, GLASGOW UNIVERSITY; PHYSICIAN TO OUT-PATIENTS DEPARTMENT, WESTERN INFIRMARY; VISITING PHYSICIAN, BELLAHOUSTON HOSPITAL.

THE following is a résumé of a preliminary report to the Medical Research Council on work done in an experimental investigation into the ætiology of disseminated sclerosis. The first part only of the work is referred to in this paper; it consists of observations upon the cerebro-spinal fluid in this disease.

Method of Examination.

The method employed in the examination of the cerebro-spinal fluid was as follows:—

(1) *Cell count.*—A Fuchs-Rosenthal chamber was employed and the enumeration carried out immediately on the withdrawal of the cerebro-spinal fluid.

(2) *Test for protein content.*—This was carried out by the Ross-Jones method, for details of which the reader is referred to the literature on the subject.

(3) *Wassermann reactions* of the blood and cerebro-spinal fluid before and during treatment were carried out in Professor C. H. Browning's laboratory, Glasgow University, by his assistant, Dr. Ernest M. Dunlop.

(4) *Dark-ground illumination.*—In every case the cerebro-spinal fluid was centrifugalised and examined by this method.

(5) *Colloidal gold reaction.*—The work of Zsigmondy, who found that certain colloids exerted definite degrees of protective action on the precipitation of gold suspensions by sodium chloride, suggested to Lange the application of this test to the protein of cerebro-spinal fluid. He found that normal cerebro-spinal fluid when diluted with a 0·4 per cent. solution of sodium chloride does not affect the solution of colloidal gold, whilst the fluid in disease of the central nervous system often produces characteristic changes. In preparing the gold solution and in carrying out the test it was found that the precautions recommended by J. Cruickshank[1] to ensure absolute cleanliness were essential for success, and that disregard of these precautions was likely to entail failure.

The method of carrying out the test is as follows[1]:—

Eleven perfectly clean and dry test-tubes are placed in a rack. To the first 0·9 c.cm. of a 0·4 per cent. solution of sodium chloride is added, and to each of the others 0·5 c.cm. of the cerebro-spinal fluid is now added and shaken up. Of the resulting mixture 0·5 c.cm. is withdrawn and added to the next tube in the series. This in turn is shaken up and 0·5 c.cm. withdrawn and added to the next tube, and this process is repeated right down the series. This gives a dilution of cerebro-spinal fluid of 1:10, 1:20, 1:40, &c. To each tube 2·5 c.cm. of colloidal gold solution are added, and the colour changes, if any, are noted in an hour, and again in 24 hours. The colloidal gold must be neutral in reaction, perfectly clear by transmitted and by reflected light. In the flask it is a deep red colour. In a test-tube it appears pink. The final criterion of the suitability of a specimen of colloidal gold for testing cerebro-spinal fluid is: (*a*) That it should give a paretic reaction (vid. inf.) with the cerebro-spinal fluid from a case of general paralysis; (*b*) that it should show no change with a normal fluid; (*c*) that 5 c.cm. should be completely precipitated in one hour by 1·7 c.cm. of a 1 per cent. solution of sodium chloride; and (*d*) that it should be neutral to 1 per cent. alizarin red in 5 per cent. alcohol.[2 3 4]

Types of Reaction.

Various types of reaction may occur. These fall into three groups—viz., paretic, luetic, and meningitic. These names were employed before the test had been widely applied in diseases other than syphilis. They must be accepted as arbitrary terms and not necessarily carrying any ætiological significance as their name might imply.

(1) *Paretic type of reaction.*—Complete precipitation of gold occurs in the first 3–6 tubes on standing for 24 hours, and the remaining tubes down to the 8th show varying degrees of purple.

(2) *Luetic type of reaction.*—Varying degrees of purple are found from the 2nd to the 6th or 7th tubes, but complete precipitation does not occur.

(3) *Meningitic type of reaction.*—The colour changes occur further down in the series, tubes 7 and 8 being chiefly affected, the tubes to the left of the middle line usually remaining unaltered.

The different colour changes occurring in the individual tubes may be indicated by numbers, viz.:—

5 represents a tube *in which complete coagulation* and precipitation of gold has occurred, leaving the supernatant fluid quite colourless.
4 represents a greyish-blue colour.
3 ,, deep blue ,,
2 ,, reddish-purple ,,
1 ,, bluish-red ,,
0 ,, tube without colour change.

Examination of the Cerebro-spinal Fluid in Disseminated Sclerosis.

Forty-one cases of disseminated sclerosis were examined. All save two gave a luetic or paretic type of reaction to colloidal gold. It is interesting to note that these two cases had been clinically diagnosed as arterio-sclerosis simulating disseminated sclerosis, in one case by Professor T. K. Monro, in the other by myself. Five cases gave a paretic curve, the remainder produced a luetic reaction. The average cell count was five, the type of cell a small lymphocyte. In every case the cerebro-spinal fluid was centrifugalised and examined by dark-ground illumination. In two cases doubtful, actively motile spirochætes were observed. Attempts to stain them were unsuccessful, and the result was accordingly regarded as negative. In all the other cases of this series dark-ground illumination yielded no result.

Protein content.—The Ross-Jones test was positive in 7 cases, or 17 per cent.

Wassermann reaction.—Positive in 9 cases. Positive in blood and cerebro-spinal fluid in 4 cases; positive in blood and negative in cerebro-spinal fluid in 2 cases; positive in cerebro-spinal fluid and negative in blood in 2 cases. In 1 case it was positive in cerebro-spinal fluid and the blood was not examined.

Diagnosis of Disseminated Sclerosis.

The recognition of this disease presents little difficulty if the diagnosis be limited to cases in which we can demonstrate spastic paraplegia, intention tremor, scanning speech, primary optic atrophy and nystagmus. By such a limitation, however, we would recognise only what is in reality the terminal stage of the disease, a stage which it has required months or years to reach and which possibly by no means all cases attain. Most clinicians would assent to a diagnosis of disseminated sclerosis in a case where all the above-mentioned signs were present with the exception of, say, optic atrophy or nystagmus. The question therefore arises as to how many and which of the cardinal signs are necessary to enable us to establish a diagnosis. Great stress has been laid by most writers on the extensor plantar reflex, but the only sign which I have found constantly present in the above series is the absence of the abdominal reflex, either unilaterally or bilaterally. It has therefore been considered advisable for the objects of this research to apply a provisional diagnosis of disseminated sclerosis to the following groups of cases:—

(1) Cases showing spastic paraplegia, absent abdominal reflexes, and one or more of the other classical signs of disseminated sclerosis. Thirty-three cases fall into this group.

(2) The primary lateral sclerosis or spastic paraplegia group with a negative Wassermann reaction, a positive colloidal gold reaction, absent abdominal reflexes, and the absence of any sign of other organic disease. Six cases fall into this group.

(3) Cases of spastic monoplegia giving a luetic curve to colloidal gold in the cerebro-spinal fluid, with a negative Wassermann reaction and no signs of other organic disease. Two cases in the series fall under this heading, and it is interesting to note that one of these was subsequently admitted with primary optic atrophy.

(4) Cases of primary optic atrophy with a negative Wassermann reaction in blood and cerebro-spinal fluid. Of these so far I have had no cases, but it is desired to emphasise the necessity of investigating carefully cases of so-called "idiopathic" optic atrophy. The colloidal gold reaction of such cases should be studied and the question of treatment carefully considered (vid. inf.).

Ætiology of Disseminated Sclerosis.

Until quite recently nothing has been known of the ætiology of this disease, which has always been regarded as incurable and fatal.[5] The statement is made by most writers on the subject that disseminated sclerosis is not due to syphilis, though this is denied by Jacobsohn.[6] There is no doubt that the great weight of clinical evidence is against a syphilitic basis for the disease. The bulk of the cases of disseminated sclerosis appear to arise in young and otherwise healthy adults with no signs or history of specific infection, congenital or acquired. The occasional occurrence of a positive Wassermann reaction may possibly be due to coexistence of the two diseases.

There have recently been circumstantial claims by continental writers to have reproduced disseminated sclerosis experimentally, and to have *demonstrated* a spirochætosis in the inoculated animals (Kuhn and Steiner[7]), and Siemerling[8] has discovered spirochætes in the brain of a patient who had died of the disease. Still more recently G. Schuster[9] has found fine spirochætes in the lower layers of the cortex in a case of disseminated sclerosis. There are, in addition, certain clinical phenomena which appear to me to be of interest when considered in the light of a spirochætal origin of this disease. In both neuro-syphilis and disseminated sclerosis primary optic atrophy occurs, and though the type of lesion is different in the two diseases the site of selection of the virus is the same. In both diseases transient ocular palsies, as shown by a history of diplopia, occur. In tabes this frequently goes on to permanent external ocular palsy, a phenomenon rarer in disseminated sclerosis, but present in two cases of my series. Head and Fearnside,[10] in their research on syphilis of the nervous system, state:—

> "*Of all the* root areas which appear in syphilis those from the seventh thoracic to the first lumbar are the most frequent. These roots carry the afferent paths from the liver, kidney, suprarenal, and testicle, organs above all others liable to be crowded with spirochætes."

With reference to this fact I would desire to emphasise the constant absence of the abdominal reflex in disseminated sclerosis; this reflex arises from segments ninth thoracic to first lumbar.

In view of all these facts it would appear that the time has now arrived when *spirochæticidal treatment* should be given a fair trial in disseminated sclerosis, more especially as recent research has proved that organic arsenical preparations reach the cerebro-spinal fluid in fair concentration.[11] Salvarsan was empirically employed with success in rat-bite fever before the discovery of the causative leptospira.

The form of treatment adopted in this investigation was on modern antispecific lines, and was commenced in December, 1919. The treatment comprised routine intravenous administration of novarsenobillon extending up to 20 or more injections. This was combined with the oral administration of biniodide of mercury and more recently with intramuscular injections of intramine. Severe reactions were rarely noted. Hyoscine was used with beneficial results in cases where the tremors and general nervousness were marked.

Eighteen cases coming under Group 1 have undergone complete courses of treatment. Nine have shown no improvement whatever. In the other nine cases some definite improvement has been noted. Of these one case (vid. inf.) showed apparent recovery, but this may have been due to one of the natural remissions of the disease which render the study of disseminated sclerosis so baffling a problem. Decrease in the spasticity of the legs, regain of bladder control where this has been previously partially lost, and increase in muscular power were the points chiefly noted. In Group 2 three cases were treated and all appeared greatly to benefit. These cases on admission had markedly spastic gait and could walk only with the help of two sticks. On discharge they could walk without support and their gait was apparently normal. One case in Group 3 was treated and showed great improvement as regards spasticity, gait, and muscular power, accompanied by a slight gain in the circumference of the limb. Patients subsequently re-examined have frequently complained of symptoms similar to the phenomena of intermittent claudication. They state that they can walk easily a certain distance, but complain of weakness and spasticity of the legs coming on suddenly and preventing them from going further without rest.

Modifications of the Colloidal Gold Reaction.

In 16 cases under treatment repeated examinations have been made of the cerebro-spinal fluid. In all modifications of the colloidal gold reaction have been found to occur. These may be summarised as follows. A paretic curve becomes luetic under neosalvarsan administration. The discoloration in the tubes giving a luetic curve becomes fainter, and the number of tubes involved becomes progressively less. In one case a completely negative result was ultimately obtained. Two examples of actual readings are appended:—

(1) C. R. Colloidal gold reading before treatment...	5 5 4 4 3 2 1 0 0 0 0
19 injections of 0·45 gr. N.A.B. were given; final colloidal gold reading as follows	3 4 4 4 1 0 0 0 0 0 0
(2) J. McM. Colloidal gold reading before treatment...	2 2 3 3 2 1 0 0 0 0 0
15 injections of 0·45 gr. N.A.B. were given; final colloidal gold reading	0 1 2 1 0 0 0 0 0 0 0

It is of interest to note that in the course of this investigation similar modifications of the colloidal gold reaction have been observed in a large series of cases of neuro-syphilis under neosalvarsan treatment.

The case referred to above, in which apparent recovery resulted, is as follows.

G. H., aged 23. Pensioner.—Admitted 12/1/20, complaining of stiffness and weakness of legs of two and a half years' duration.

History of onset: In the summer of 1917 he was capsized in a whaler and immersed for 10 minutes in the sea in cold weather. A few weeks later he complained of stiffness and weakness of the right leg on route marching. His previous health had been uniformly good, and his family history contained no fact of note. He stated he had never suffered from venereal disease, was moderate in his consumption of tobacco, and an abstainer from alcohol.

Condition on admission: A well-developed, well-nourished man of 23. His chief complaint was weakness and stiffness of his legs.

Central nervous system: Legs markedly spastic with considerable muscular weakness. Knee-jerks: right +++, left ++. Tendo Achillis jerks both +. Patellar clonus marked on right, could not be elicited on left. Plantar reflex left flexor, right doubtfully extensor. Epigastric and superficial abdominal reflexes absent. Arms: muscular power apparently unimpaired; supinator jerks +, other tendon reflexes normal. Organic reflexes normal. Eyes: pupils equal and react to light and accommodation. Consensual reaction present. Marked lateral nystagmus easily elicited; rotatory nystagmus present to a lesser degree; vertical nystagmus not elicited. O.E. left disc: distinct pallor of temporal half of disc; veins congested. Right disc: slight pallor of temporal half; nasal and inferior margins blurred.

Speech: No alteration from normal noted. Intention tremor present in both arms. Special senses: smell, taste, and hearing normal. No history of memory defect or other mental symptom. Sensory neurone: slight impairment of superficial tactile sensation over scattered areas in right leg; tactile sensation otherwise apparently normal. Pain and temperature sense normal. Muscle-joint sense normal. Stereognostic sense normal.

Cerebro-spinal fluid on admission: Fluid clear. Pressure normal. Cell count = 9. Ross-Jones test negative. Alcohol faint haze. Wassermann reaction: blood negative; c.s.f. negative.

Colloidal gold reaction: 2 3 3 3 3 1 0 0 0 0 0.

Treatment was commenced in February, 1920, and carried out on routine antispecific lines. It comprised 12 intravenous injections of 0·45 gr. N.A.B. given in series of four doses at seven-day intervals, with a period of two weeks between each series. In addition, mercurial inunction was carried out.

Colloidal gold reaction of cerebro-spinal fluid after treatment:—31/7/20: 0 0 0 0 0 0 0 0 0 0 0. (This is the only case in which a completely negative result has been obtained.)

Subsequent history: Patient subsequently reported for examination on 5/1/21. There was great improvement in his condition. The muscle tone of the legs was apparently normal. The gait appeared normal, and he stated he could walk a distance of about one and a half miles and would then suddenly complain of symptoms of fatigue and be unable to proceed further. There was very slight lateral nystagmus seen only on extreme deviation to the left and confined chiefly to the left eye. A very slight tremor at the end of a voluntary act could be elicited in the right hand only. The left abdominal reflex was weakly present and easily exhausted. The right was absent. No clonus could be elicited. The plantar reflexes were indefinite.

His general improvement was such that his pension had been stopped, and he had for several months been earning his living by continuous employment as an oil refiner—his pre-war occupation.

The following case is also of considerable interest:—

W. B., aged 22, patient of Dr. T. D. Laird, was sent into hospital 12/3/20 as a case of diabetes mellitus. He stated that his illness commenced in July, 1918, when he complained of thirst, progressive loss of weight, and marked weakness of both legs.

On admission: General nutrition fair; urine contained 3·5 per cent. sugar, urinary output 130 oz. The ferric chloride reaction was negative.

Central nervous system: Both legs markedly spastic. Knee-jerks ++. *Bilateral extensor plantar response.* Abdominal reflexes absent.

Organic reflexes: Patient gave history of occasional retention and incontinence of urine; bowel sphincter normal.

Eyes: Pupils equal and react normally. No external ocular palsy. No history of diplopia. No nystagmus. Optic fundi: O.E. discs paler than normal, and lamina cribrosa unduly distinct. Speech and special senses normal. No intention tremor.

Cerebro spinal fluid: 31/3/20. Fluid clear, pressure +. Cell count = 2. Type of cell small lymphocytes. Ross-Jones, alcohol and Nonne Apelt tests negative. Wassermann reaction of cerebro-spinal fluid negative, of blood negative.

Colloidal gold reaction: 2 3 3 3 2 2 1 0 0 0 0 (luetic reaction).

Progress of case: Starvation diet for 24 hours produced a fall in the sugar percentage from 3·5 to 0·45, and a week later, after 24 hours' starvation, the urine gave a negative reaction for sugar. On normal ward diet the sugar percentage varied from 3·5 to 5. In view of the spastic paraplegia, absence of abdominal reflexes, sphincter involvement, and early optic atrophy, a provisional diagnosis of disseminated sclerosis involving the fourth ventricle was made, and the patient was treated by mercurial inunction and intravenous injections of novarsenobillon (20 in all) and Graham's diabetic diet.

Result: A gradual but almost uninterrupted recovery was made. The cerebro-spinal fluid was subsequently re-examined on two occasions. The average cell count was 1, the protein tests and Wassermann reaction remained negative. Slight modification of the colloidal gold reaction was observed. Prior to treatment tubes 1–7 showed colour alterations (vid. sup.). On the conclusion of treatment only tubes 1–5 showed a reaction and the colour alterations were less marked, the readings being as follows: 1 2 2 2 1 0 0 0 0 0 0.

Clinical result: The sugar completely disappeared from the urine. The legs became much less spastic and the muscular power improved. The plantar reflexes were no longer constantly extensor. The abdominal reflexes remained absent.

On discharge (30/11/20) the patient could walk with an apparently normal gait without the help of a stick, and the urine had been free from sugar for over a month. I was subsequently informed (8/1/21) by Dr. Laird that the urine was still constantly free from sugar, and the patient stated that he was enjoying a practically normal diet and appeared to have regained his health.

Summary and Conclusion.

(1) The cerebro-spinal fluid picture in disseminated sclerosis is as follows: a normal cell count, a negative Wassermann reaction, a luetic or paretic reaction to colloidal gold, and in most cases (83 per cent.) a normal protein content.

(2) The absence of a positive Wassermann reaction in the great majority of cases and the absence of pleocytosis are in accordance with the view that this disease is not of syphilitic origin.

(3) On the supposition that the origin might be spirochætal treatment was carried out by spirochæticidal drugs. In practically every case under treatment modifications towards a negative result of the colloidal gold reaction were noted.

(4) As regards clinical effects of such treatment, no improvement resulted in advanced cases of the disease, but prolonged treatment produced amelioration of early cases, and in one or two instances the results were marked.

(5) With reference to early diagnosis, emphasis is laid on the evidence of the cerebro-spinal fluid picture and the absence of the abdominal reflex.

I am indebted to the Medical Research Council for defrayment of the expenses of this investigation. I also desire to express my thanks to Dr. Wilfrid H. Scott for help in connexion with the clinical work, and to Mr. J. A. W. McCluskie for assistance in the colloidal gold technique.

ROYAL SURGICAL AID SOCIETY.—At the meeting of the committee held on Feb. 15th Mr. Samuel Watson, who has just retired from the offices of treasurer and chairman of committee, was presented with an illuminated address, recognising his services to the society. He has served it for 51 years, having joined first as a member of the committee in 1869, becoming a trustee in 1895, and having been chairman and treasurer since 1902.

ANALYSIS OF THE GASTRIC CONTENTS
OBTAINED BY THE FRACTIONAL METHOD.

BY SYDNEY W. COLE, M.A. CANTAB.,
AND
W. J. ADIE, M.B. EDIN., M.R.C.P. LOND.

(From the Pathological Institute, Charing Cross Hospital, and the Biochemical Laboratory, Cambridge.)

REPORT TO THE MEDICAL RESEARCH COUNCIL.

THE secretory and motor activities of the stomach are now being studied by a considerable number of investigators stimulated by the possibilities of the "fractional method" introduced by Rehfuss and Hawk.[1] It is desirable that the results obtained by different workers should be capable of interpretation by others in the light of their own findings. With the large number of methods of analysis available it is unfortunate that a standard technique has not yet been uniformly adopted. The purpose of this paper is to suggest simple yet accurate methods of analysis and to invite criticisms and suggestions from other workers in order to secure uniformity of analysis and expression of results.

The following points are discussed below: (1) the nature of the meal; (2) the method of expressing results; (3) the determination of "free" acidity; (4) the determination of "total" acidity; (5) the determination of total and mineral chlorides, and thus of the active and combined hydrochloric acid; (6) the determination of the enzymes present.

Nature of the Meal.

The end-points of the titrations are much sharper if a *colourless* filtrate can be obtained. For this reason in particular we urge the adoption of the oatmeal test breakfast as a standard. It is readily prepared according to the method suggested by J. A. Ryle[2]:—

> "Mix two tablespoonsful of breakfast oatmeal with one quart of water. Boil slowly down to one pint. Strain through muslin. Add salt to taste and give warm."

We do not recommend the addition of the salt, as the content of sodium chloride may well prove to be of great importance in connexion with the diagnosis of carcinoma. It is our custom to get the patient to swallow the tube ten minutes before taking the meal. This allows time for the subject to recover his composure. The amount withdrawn need not exceed 7 to 10 c.cm. at each interval, but it is advisable to withdraw 12 to 15 c.cm. at the end of the first hour if an estimation of total and mineral chlorides be desired. The best filter paper in our experience is Whatman's No. 1, 9 cm. diameter. Notes should be made as to the presence of blood, mucus, and bile.

Method of Expressing Results.

The usual method of expressing these in terms of c.cm. of 0·1 normal per cent. is most convenient, and, in our opinion, should be extended to the analysis of total and mineral chlorides as well as to those of free and total acid.

Determination of "Free" Acidity.

The first point to consider in this connexion is what we mean by "free hydrochloric acid." It is usually regarded as that part of the hydrochloric acid which is not combined with protein or any other potential base, and which is ionised to the same extent as it would be in simple aqueous solution; that is to say, that if we have "free" HCl present in gastric juice to the extent of 40 c.cm. of 0·1 N. HCl per cent., then by diluting 40 c.cm. of 0·1 N. HCl to 100 c.cm. with distilled water we shall obtain a solution of the same hydrogen-ion concentration as that of the gastric juice. If that is so, then the problem of the estimation of the free HCl of a specimen is practically the same as that of the determination of its hydrogen-ion concentration. For the effect of organic acids and of hydrochloric acid combined with protein on the hydrogen-ion concentration of the solution when the acidity is at all high is practically negligible.

It is probable that the usual method of determining "free" acidity is to add Töpfer's indicator (dimethylaminoazobenzene) to a measured sample and to titrate with standard (0·1 N.) soda until the pink tint disappears. It is then assumed that the soda added has only neutralised the "free" acid, and does not react with organic acids or with combined hydrochloric acid. This assumption is quite unwarranted. Töpfer's indicator changes from a pink to a yellow between the ranges of pH = 2·9 to pH = 4·0, and it is probable that most workers add soda until the reaction is about pH = 3·3, corresponding to a hydrogen-ion concentration of $5{\cdot}10^{-4}$.

Now suppose we are titrating a fluid from the stomach which actually has 50 c.cm. per cent. of free 0·1 N. HCl and which also contains a certain amount of hydrochloric combined with the peptones. If our definition is correct, the hydrogen-ion concentration will be the same as that of a simple solution of 50 c.cm. of 0·1 N. HCl in 100 c.cm.—i.e., the pH is about 1·33. If the gastric fluid be titrated with soda this does actually combine with the free hydrochloric acid until a point is reached when there is about 10 c.cm. of 0·1 N. free HCl present in 100 c.cm. of the mixture and the pH is about 2. But from this point onwards in the titration anomalous results are obtained. The power of the protein to combine with hydrochloric acid decreases as the hydrogen-ion concentration is lessened and we approach nearer to the iso-electric point of the protein. This naturally varies with the nature of the meal, the activity of the pepsin, and the duration of digestion, but is probably between pH = 4 and pH = 6. Also the mass of the free hydrochloric is now relatively small compared to that of the combined hydrochloric acid, so that from pH = 2 onwards the soda added partially neutralises the free HCl and partially the combined HCl. It follows that the result of titrating to Töpfer's indicator is a very imperfect guide of the actual amount of free HCl originally present. The higher the concentration of peptone the greater is the error, which may be as great as 40 per cent.

Günzberg's method of titrating with soda or by diluting with water until a reaction with a mixture of phloroglucin and vanillin is not obtained does seem to give very reliable results, but the method is tedious and difficult to apply when only about 2 c.cm. of the fluid can be spared for the analysis. The best indicator for the purpose is undoubtedly thymolsulphone-phthalein ("thymol-blue"), which was introduced by W. M. Clark and H. A. Lubs.[3] This has a double range. From pH. 1·2 to 2·8 it changes from red to yellow; it remains yellow from pH. 2·8 to 8·0 and from pH. 8·0 to 9·6 it changes from a green to a deep blue. Its great advantage is that it can be used with the same sample of gastric juice, first for the titration of free hydrochloric acid and then, by adding alkali until it goes blue, for the determination of total acidity. Clark and Lubs mention its applicability to stomach contents, but the method of using it was, we believe, first described by one of us.[4] The method recommended then was to titrate to pH. = 2·6, against a standard phthalate buffer solution, using the comparator described by S. W. Cole and H. Onslow.[5] This method has been used regularly by the students at the Biochemical Laboratory, Cambridge, during the past year, and by us in our earlier investigations of clinical material at Charing Cross Hospital.

A method involving the use of the same indicator was described last May by A. T. Shohl and J. H. King.[6] They determine the hydrogen-ion *concentration by the colorimetric* method against a series of solutions of known pH. These are prepared from 0·1 N. HCl and 0·1 N. KCl, according to the directions of Clark and Lubs.[3] From the pH thus found, the normality of the free hydrochloric acid present can be ascertained and so the number of c.cm. of 0·1 N. HCl per cent.

Our objections to the method are that it is not sufficiently accurate. The sensitivity of the indicator is by no means constant over the whole range. At pH = 1·4 the change in tint corresponding to a change of 0·1 pH is by no means easy to see, and yet this corresponds to a difference of about 10 c.cm. of 0·1 N. NaOH per cent. It is true that they recommend dilution with an equal volume of water *if the* sample be more acid than pH = 1·6, but by this procedure the probable error is multiplied by 2 or even by 4 and is still too large. Further, the effect of such a dilution on the electrolytical and hydrolytical dissociation of combined hydrochloric acid is, at present, largely a matter of conjecture. At the same time, we are of the opinion that the method is workable, and if dilution be made to the most sensitive point of the indicator good results are obtained.

As stated above, we originally titrated the gastric contents to a reaction of pH = 2·6, using thymol-blue as the indicator and marking the end-point by comparison with the colour of a phthalate – HCl buffer mixture of pH = 2·6 similarly treated with thymol-blue. The results obtained on mixtures of commercial peptone and *hydrochloric* acid when compared with those obtained by Günzberg's method were so close that we seemed justified in using it. We now find that the agreement was more or less accidental. We were using a very low content of peptone (0·2 per cent.) and titrating with a very dilute soda (0·03 N.). We failed to appreciate the significance of the considerable increase in volume of fluid, and made no allowance for it in our calculation. When the percentage of peptone is increased to what is normally found in the stomach contents the error is appreciable and is always such that the amount of free HCl apparently found by titration to pH = 2·6 is greater than that found by Günzberg's method.

The result of titrating mixtures of peptone and hydrochloric acid by different methods is presented in the table, which is only one from a series of similar experiments. In the case of the thymol-blue titrations 5 c.cm. of the various mixtures were treated with thymol-blue and titrated with 0·1 N. soda containing thymol-blue and prepared according to the directions given below. This was added until the tint of the mixture was judged to be the same as that of a solution of hydrochloric acid of known strength, also containing the same proportion of the indicator. The calculation of results is as follows: suppose 5 c.cm. of the mixture require x c.cm. of the 0·1 N. soda to bring the reaction to that of 0·01 N. HCl. Then 100 c.cm. would require 20 x c.cm. of 0·1 N. soda. The total volume is (100 + 20 x) c.cm., and since 100 c.cm. of 0·01 N. HCl requires 10 c.cm. of 0·1 N. soda to neutralise it then (100 + 20 x) c.cm. requires 10 + 2 x c.cm. of soda. So the total amount of 0·1 N. soda required for 100 c.cm. of the original solution is 10 + 22 x c.cm. and the free HCl is expressed as (10 + 22 x) c.cm. of 0·1 N. HCl per cent. Similar calculations hold good for other end points in this series. The figures under "Günzberg" and "Töpfer" were obtained by the usual technique of titration with 0·1 N. soda. "Total" acidity was obtained by titration with 0·1 N. soda containing thymol-blue, as described below:—

End-point of titration in c.cm. of 0·1 N. HCl per cent.	Thymol-blue.							Günzberg	Töpfer	Total acidity.
	30	25	20	15	10	5	2·5			
Corresponding pH	1·56	1·64	1·74	1·86	2·0	2·3	2·6	–	–	–
50 c.cm. 0·1 N. HCl—										
+ 50 c.cm. of water.	51	50	51	50	50	50	50	51	50	52
+ 50 c.cm. 0·4 peptone	45·5	47·5	45·5	45	44	45	45·5	44	49	53
+ 50 c.cm. 0·8 ..	38	39	38·5	40	38·5	40·5	42·5	39	47·2	55
+ 50 c.cm. 1·2 ..	32	33	31	32	32	34·5	37	32	44·6	58
+ 50 c.cm. 1·6 ..	—	—	25	27	27·5	30	24	27	42	60

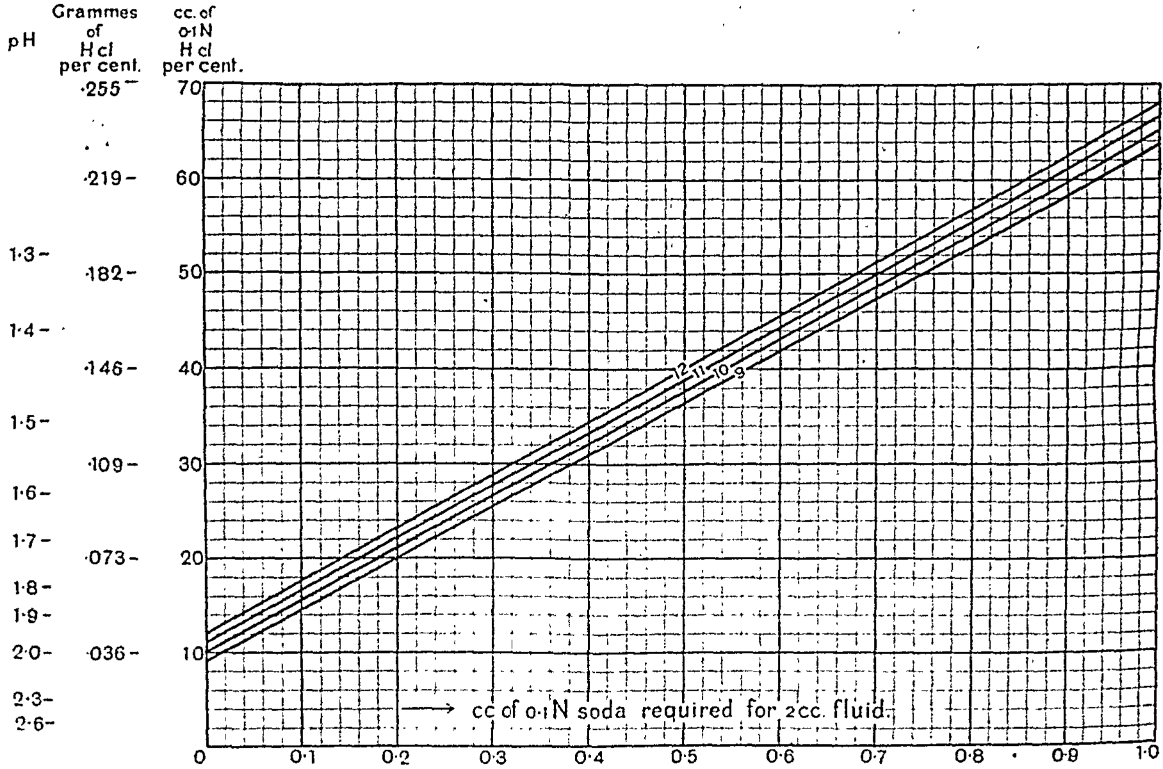

Chart for determination of free HCl.

It will be seen that the results of the thymol-blue titrations are fairly constant until pH = 2 is reached, but that further additions of soda are no measure of the amount of free HCl present, especially in the presence of any considerable amount of peptone. Töpfer's method is seen to give much too high a figure, the error being 11 per cent. in the presence of 0·2 per cent. peptone and 55 per cent. in the presence of 0·8 per cent. peptone. Günzberg's method gives astonishingly good results, which is in agreement with those who have compared it with the electrical method. Why this should be so is not very clear. Probably the increased concentration of peptones, &c., that takes place on evaporation with the reagent results in more of the HCl binding with the protein. So that a solution which in the cold has a hydrogen-ion concentration higher than that required for a positive reaction fails to give the test on evaporation.

The technique we have finally adopted is to treat 2 c.cm. of the clear filtrate with thymol-blue, and to titrate it with 0·1 N. soda containing thymol-blue from a microburette until the colour is the same as that of one of a series of standard solutions of hydrochloric acid which have been treated with the same proportion of the indicator. Knowing the volume of soda that has been used to bring the reaction to a given point, the original concentration of free acid is determined by calculation or from a curve. The end-points we have chosen are those of 0·012, 0·011, 0·010, and 0·009 N. HCl. These are selected from the fact that the indicator is very sensitive over this range, and that by titrating up to this point one gets a real measure of the free hydrochloric acid. Should the concentration of free HCl be less than 9 c.cm. of 0·1 N. per cent., subsidiary standards are readily prepared by dilution of those ready to hand. A further advantage of the method is that the same sample is subsequently titrated with the same soda for the estimation of total acidity.

Solutions and Apparatus Required.

(1) *Four Standard Acids*, 0·012 to 0·009 N. Measure 12, 11, 10 and 9 c.cm. respectively of 0·1 N. HCl into four labelled 100 c.cm. measuring flasks. Make the volumes up to the marks with distilled water and mix well.

(2) *Thymol-blue*, 0·1 per cent. aqueous solution. A stock 1·2 per cent. solution of the mono-sodium salt can be purchased. 10 c.cm. of this are diluted with 100 c.cm. of

distilled water and the colour noted. It should be a reddish orange. If it is blue, decinormal sulphuric acid should be cautiously added until the desired tint is obtained, and the volume then made up to 120 c.cm. The diluted solution is conveniently kept in a bottle fitted with a rubber cork through which passes a Dreyer's dropping pipette which is fitted with a rubber teat. In measuring the indicator it is essential to hold the pipette strictly vertical, and not to allow the drops to fall more rapidly than one per second.

(3) *Decinormal Soda containing Thymol-blue.*—For the estimation of total acidity it is desirable to work with CO_2 – free soda, which can be prepared according to the directions of Clark and Lubs.[8] A full account will be found in S. W. Cole's "Practical Physiological Chemistry."[7] If this is not available ordinary standard soda can be used. It is perfectly satisfactory for free HCl, but gives a rather evanescent end-point for total acidity. A stock solution of 0·2 N. is most convenient. Measure 25 c.cm. of this into a stoppered 50 c.cm. volumetric flask, add 50 drops of the 0·1 per cent. thymol-blue, and make up to the mark with cold, recently boiled, distilled water. Mix thoroughly and store in a dark cool cupboard when not in use.

(4) *A 2 c.cm. microburette* that is filled by suction has been designed by one of us (S. W. C.) and can be obtained from Messrs. Baird and Tatlock.

(5) *Test-tubes of the Same Internal Diameter.*—We use tubes 5 × ⅝ in., which are calibrated by noting the level reached after the addition of 10 c.cm. of water.

Method: Measure 3 c.cm. of the standard acids into four of the tubes, labelled 12, 11, 10, and 9 respectively. To each add three drops of the thymol-blue. Measure 2 c.cm. of the clear filtered gastric contents into another tube by means of an Ostwald pipette. Add two drops of the indicator. If any appreciable amount of free HCl is present a bright carmine colour is obtained. Titrate with the 0·1 N. NaOH until the colour is very slightly lighter than the "12" acid. Match the colour exactly with one of the remaining tubes, adding a trace more of the soda if necessary.

Calculation.—If x c.cm. be the volume of 0·1 N. soda required, the free HCl in c.cm. of 0·1 N. acid per cent. is 56 x + 12, 55·5 x + 11, 55 x + 10, and 54·5 x + 9 for the 12, 11, 10, and 9 tubes respectively.

These volumes are most conveniently read from the chart here given, which also shows the pH of the solution and the HCl in grammes per cent.

Should the free HCl be between 9 and 2·5 of 0·1 N. per cent., the amount is best found by diluting the standard acids with water, adding one drop of thymol-blue per c.cm. until the tint of the diluted acid is the same as that of the sample. The c.cm. of 0·1 N. acid per cent. is then readily determined by a simple calculation. Thus, if 3 c.cm. of the "9" acid + 2 c.cm. of distilled water matches the sample, then the acidity is 3/5 x 9 = 5·4.

Determination of "Total" Acidity.

The same 2 c.cm. sample of gastric fluid used for the estimation of free HCl is titrated with the 0·1 N. soda till the mixture turns blue. To obtain uniformity of results we titrate to a reaction of pH = 8·8. This can be prepared according to the directions of Clark and Lubs,[8] or can be purchased from Messrs. Baird and Tatlock or other agents. 3 c.cm. of this are measured into a tube similar to those previously used, and three drops of the indicator are added. The gastric fluid is then titrated with the 0·1 N. NaOH containing thymol-blue until the colour matches that of the standard. If the standard of pH = 8·8 is not available, the mixture should be titrated to a full blue. The calculation is obvious; the total volume of 0·1 N. soda used for the two titrations multiplied by 50 is the total acidity in terms of c.cm. of 0·1 N. acid per cent.

Determination of Total and Mineral Chlorides.

In the light of the work of G. Graham[9] the estimation of the ratio between active and mineral chlorides is of considerable importance in the diagnosis of carcinoma of the stomach. The time and attention required for the analysis is so great that it is not usually possible to attempt it on more than one or two fractions. As mentioned above, we usually withdraw rather more fluid at the 1 hour and 1¼ hour periods to give us a sufficient amount of material for analysis. The technique best adapted to the purpose is a modification of F. C. McLean and D. van Slyke's method,[10] for which the following reagents are required:—

(1) Standard silver nitrate 0·04 N. Dissolve 6·8 g. of pure fused silver nitrate in about 650 c.cm. of distilled water. Add 250 c.cm. of pure concentrated nitric acid (sp. gr. 1·42). Allow to stand for some time and then make the volume up to exactly one litre with distilled water—

1 c.cm. = 0·0046 g. HCl.

(2) Sodium citrate and nitrite mixture.

Crystalline sodium citrate ($Na_3C_6H_5O_7 + 5\frac{1}{2} H_2O$)	446 g.
Sodium nitrite	20 g.
Distilled water to make	1000 c.cm.

It is essential that the reagents be quite free from chlorides. We have obtained a few satisfactory samples of citrate, but the majority have to be recrystallised once or twice. The mixture is made by adding the solids to about 500 c.cm. of distilled water, dissolving by heating on the water-bath and making up to 1000 c.cm. with distilled water after cooling.

(3) Soluble starch 2 per cent. To 90 c.cm. of boiling distilled water add 2 g. of the starch suspended in 10 c.cm. of cold water. Stir and boil. Transfer to test-tubes, plug with cotton wool, and sterilise for 10 minutes in the steamer. A supply of the starch in good condition is thus always ready for use.

(4) A standardised solution of potassium iodide 0·02 N: Dissolve 3 g. of pure potassium iodide in distilled water and make the volume up to 1 litre. Mix thoroughly. Standardise this as follows. Measure 10 c.cm. of the silver solution into a small flask. Add 10 c.cm. of the citrate mixture and about 1 c.cm. of the soluble starch. Titrate with the iodide from a burette until a blue tint is obtained. With good quality reagents the end point is sharp to a single small drop, but a little experience is necessary to recognise it. The iodide has to be adjusted by dilution with water until 2 c.cm. of it correspond to 1 c.cm. of the silver. If x c.cm. are required for 10 c.cm. of silver add 5 (20 – x) c.cm. of water to every 100 c.cm. of the remainder.

Method for Mineral Chlorides.—Measure 2 c.cm. of the clear filtrate into a small, flat-bottomed, lipped silica crucible. Evaporate to complete dryness on a boiling water bath. Ignite over a Bunsen burner to a dull-red heat. Allow to cool, add about 10 c.cm. of distilled water, and cautiously heat to nearly boiling point by means of a small flame (micro-burner). Allow to cool. Rub up well with a small glass rod and transfer to a 50 c.cm. measuring flask. Extract twice more with successive portions of 10 c.cm. each of cold water. Add 5 c.cm. of the silver nitrate, make up to the mark with distilled water, and mix thoroughly. Filter through a dry 9 cm. No. 1 Whatman paper into a clean dry flask or boiling tube. Should the first portions of the filtrate come through cloudy they must be re-filtered. Measure 25 c.cm. of the clear filtrate into a small Erlenmayer flask, add 2·5 c.cm. of the citrate and 3 or 4 drops of the starch. Titrate with the iodide from a 5 c.cm. microburette until the first blue tint is obtained.

Method for Total Chlorides.—This is exactly the same as the above, but before starting the evaporation about 0·4 c.cm. of a saturated (20 per cent.) solution of sodium carbonate is added. If there is not enough filtrate available the 2 c.cm. that have been used for the estimation of total acidity can be taken, the tube being carefully washed out with small amounts of distilled water. In this latter case there is no necessity to add more than a single drop of the sodium carbonate.

Calculation of Results.—(5 – volume of iodide used) x 20 = c.cm. of 0·1 N. chloride per cent. Total chlorides less mineral chlorides gives the "active HCl" or "secreted chloride." This should correspond fairly closely with the total acidity, the latter being considerably greater in cases of hypoacidity where organic acids have been formed by fermentation. In a few cases the active HCl works out to be greater than the total acidity. This is probably due to the presence of a certain amount of ammonia, which volatilises away as ammonium chloride during the incineration of the residue for mineral chlorides. The mineral chlorides being thus too low, it follows that active HCl is too high. But in our experience this is a relatively rare event. Yet Schryver and Singer[12] only found the total acidity higher than the active HCl in 34 per cent. of their 125 cases.

According to Graham,[9] the ratio $\frac{\text{active HCl x 100}}{\text{mineral chlorides}}$ is very low in carcinoma and very high in gastric ulcer. As far as we have gone at present we are in complete agreement with him. It is obviously useless to take this ratio if there is any indication of a previous flow of alkaline material from the duodenum, or if the resting residuum of the stomach has not been removed before giving the meal.

Determination of the Enzymes Present.

In the present state of our knowledge it is probable that an estimation of pepsin is only of value in enabling us to distinguish between true achylia and the achlorhydria that may be seen in some cases of carcinoma. In true achylia the enzymes are absent, but in the few cases of gastric carcinoma in which we have found achlorhydria we have also found pepsin and rennin. Opinions as to the identity of gastric rennin are by no means unanimous, but it is our firm conviction that a milk-clotting enzyme distinguishable from pepsin is secreted by the adult human stomach. The evidence on which this opinion is based rests on the work described in Cole's "Practical Physiological Chemistry," sixth edition, p. 209. We are making a careful study of the stability and action of the enzymes and hope to publish the results in a later communication.

THE SKIN AND ITS REACTIONS.[1]

BY ARTHUR J. HALL, M.D. CAMB., F.R.C.P. LOND.,

PROFESSOR OF MEDICINE, UNIVERSITY OF SHEFFIELD.

THE skin differs from all other organs in that it is on the surface of the body. This position necessarily carries with it certain duties which a surface organ alone can perform; these duties may be considered under two heads, as they are related to things occurring: (*a*) outside the body; and (*b*) inside the body.

(*a*) *Outside the body.*—Under this heading are four functions of the skin. (1) It receives all direct injuries from without, being thus the first line of defence; (2) it is the first tissue to be chilled or warmed by changes in external temperature, being thus the outpost for heat regulation; (3) it alone comes in contact with other bodies, welcome or unwelcome, being thus the intelligence department of the central nervous system, and through the latter is in close association with the sex organs; (4) it is the only tissue visible to others, and is therefore available for attracting or repelling them, or for evading them by disguise: here the protective and sex functions again come into association. In all these ways the skin is chiefly a receptive organ, and although it is intimately associated with certain inner organs the relationship is primarily from without inwards.

(*b*) *Inside the body.*—Under this heading the conditions are very different. If the skin formed a complete envelope to the body it would necessarily have the two vitally important domestic functions of absorbing nutriment and eliminating waste, and its relations with all internal organs would be very intimate; but it takes practically no part in the former process, and its action in the latter is confined almost entirely to elimination of a certain proportion of water and salts. Except as a heat-regulating mechanism the skin plays no obvious part in the general domestic metabolism of the internal organs. Regarded from a physiological standpoint, its importance as a receptive organ quite outweighs that relating to the domestic functions of the body.

Relation of Skin Diseases to Internal Disorders.

In considering the relation of skin diseases to internal disorders these points should, in my opinion, always be borne in mind: (1) That the skin is not merely a covering, but itself an important organ; (2) that its duties relate chiefly to events occurring outside the body; (3) that while some of these reactions are local processes in the skin, the bulk of them are controlled and regulated by the central nervous system, and are of the nature of reflex actions; (4) that like all other reflex actions they are capable of excitation from places other than the outside, and of being modified by the condition of the central nervous system resulting from changes in the internal organs. In this sense they must depend upon the condition of the body as a whole at any given time. Greater progress may result if we keep in view this individuality of the skin as an organ, and study more closely its reactions, than if we regard the skin as a kind of screen upon which the clinician views what is going on in the organs beneath.

I believe that many changes in the skin now attributed to internal disorders are capable of explanation as natural reactions of the skin to definite stimuli. Some of these, such as pigmentary changes, probably date back to remote periods, and are merely remains of functions once important, and now not only obsolete but actually inconvenient. There are, of course, many skin disorders which are obviously due to internal affections—for instance, the rashes of the exanthemata. But even here the individuality of the skin cannot be overlooked. We know that the rash of small-pox is due to a poison circulating in the whole body, but we do not believe that the liver or the spleen are simultaneously covered with papules which go through the well-known stages of the rash seen on the skin. All this is a reaction peculiar to the skin and not improbably modified by external conditions.[2] A list could easily be made of so-called skin diseases due to changes from within the body; it would include the exanthematous rashes, syphilides, herpes zoster, purpuric eruptions, &c.; such a list of agreed certainties would not be very long. It would also be easy to make a similar and rather longer list of affections certainly due to external causes, including scabies, pediculosis, tinea, impetigo contagiosa, burns, corns, &c.

There would still remain a considerable number of skin diseases about the origin of which opinions would probably differ; numerous common affections—among them many of the conditions once called eczema—would here be included. No doubt some of this uncertain group will one day be proved to arise from internal or external causes; meanwhile, in trying to ascertain the truth, the part which the skin itself plays must always be borne in mind, and it is to one aspect of these skin reactions that I shall limit my remarks.

Widespread Dermatitis Developing during Local Treatment.

We must all be painfully familiar with the fact that every now and then a patient who is being treated for some trivial local eruption—a varicose dermatitis of the leg or a sore place on the hand—suddenly and quite unexpectedly develops a widespread acute weeping dermatitis. Although the area around the original site is severely affected, yet the dermatitis is not limited to that area; it affects distant parts, with intervals of clear skin. There is usually a distinct rough symmetry about the eruption; if it is on one segment of one limb it appears on the corresponding segment of the other. It is also on corresponding surfaces of these segments. Often all four limbs and the face are involved. This sudden outbreak is usually attributed to some cause from within. The patient thinks it is due to something he has eaten; the doctor, according to his particular school of thought, speaks of suppressed gout or intestinal toxæmia, whilst both agree that the patient is probably overworked and run down and needs a rest. Inquiry will usually show that the outbreak has followed shortly after the application of some "new material" to the skin. This may have been ordered by the doctor; more commonly it has been surreptitiously bought at a chemist's or presented by a kindly fellow-sufferer. Sometimes this "new application" is so apparently harmless that it is difficult to convince oneself that it can be the cause; at other times it is a substance known to be "rather dangerous to sensitive skins." In other words, if my interpretation of these cases is correct, the acute outbreak does not depend solely upon the material applied, but also upon the susceptibility of the particular individual's neuro-cutaneous reaction to that particular material or type of material.

---

[1] A paper read at a discussion of the Medical Society of London upon Skin Disease: Its Relation to Internal Disorder, held on Feb. 14th, 1921.

[2] Finsen's well-known method of preventing pustulation by keeping small-pox patients in a red room is here alluded to.

The conditions just described have certain points of resemblance to those found in dermatitis, due to a known irritant, such as primula obconica or phenylhydrazin, which are not universal irritants, as most people can handle them with safety. Yet in those whose skins are susceptible the violence and extent of the reaction far transcends the duration or extent of the contact. If a person susceptible to primula keeps away from it he will have no attacks of dermatitis. All this time he may be in excellent health in every way, but he remains susceptible. I have seen a case in which a lady successfully avoided contact with primula for 20 years, and then accidentally knocking over a vase of flowers in a friend's house, she hastily picked them up, only to find that one of them was a primula; in a few hours she was covered with an acute dermatitis. I think that this type of skin reaction to some particular kind of substance is more common than is generally recognised. Happily it is not present, and therefore cannot be called forth, in most people.

When first the phenomena of anaphylaxis were discovered there were so many features common to this and to the skin reactions here mentioned that the problem of skin idiosyncrasy seemed nearer solution. But there is obviously something more than the anaphylactic phenomena. Possibly there is some link connecting the two which time will make clear. I do not think that our knowledge of the defensive reactions of the skin is yet sufficient to carry this point further.

Acute Vesicular Dermatitis Induced by Wearing a Necklace.

The views I have expressed still lack definite experimental proof. The first step to such proof is to apply a known irritant to a limited area of the skin of a known susceptible and to produce a widespread acute dermatitis in remote areas of the skin. The difficulties of carrying out such an experiment are obviously numerous, but during the past year I met with almost the complete essentials, and the experiment was attempted. It did not succeed, but as the case presented some unusual features illustrating my point of view I shall briefly relate it.

The patient, a single woman, aged 31, came to consult me on Feb. 13th, 1920, complaining of a rash on the back of the neck. There was a transverse strip of acute vesicular dermatitis of considerable intensity extending across the nape of the neck. She asked if it could have been caused by an imitation pearl necklace, and gave me the following history: The necklace was given to her on Christmas Day, 1919. She wore it all that day from noon till bed-time, and put it on again first thing next morning. During the morning the neck began to burn and itch where the necklace was in contact; she took it off at once, and in a few hours there was an acute dermatitis which discharged freely for some days over the site, and did not disappear for three weeks. She did not put the necklace on again until the rash had disappeared, about the middle of January; she then wore it at a party from 6.30 to 9.30 P.M. Next morning the skin was irritable and the rash had appeared again in the same place. This also ran its course. The necklace was put away until Feb. 12th; then, expecting to meet the donor, she wore it at a ball from 7.30 till 11.30 P.M., and whilst still wearing it felt the irritation beginning. Next morning when I saw her the condition was as I have described above.

That the necklace produced the local dermatitis by contact with the unbroken skin was evident. There seemed no possibility of mechanical friction being the cause, as the pearls had a perfectly smooth surface. On examining an individual "pearl" the latter was found to consist of a thin hollow glass sphere with a small hole at each end of one axis; through these holes the pearls were strung on the thread. On attempting to slip the pearls along the thread it was found that they stuck, owing to the exudation of their contents. On crushing a pearl it was found to contain a wax-like material which, when warmed to body temperature, gave a greasy stain on filter paper.

It thus seems possible that the particular irritant in her case was not the smooth, solid surface of the pearl, but something put inside it to give the pearl-like appearance which exuded from the two holes on to the thread when warmed by the skin. This view seems to be confirmed by the history the patient gave of her previous skin experiences. She knew that certain greasy substances irritated her skin. Twelve years ago a well-known patent ointment, bought to apply to a sore nostril, produced a very severe and persistent inflammation over the whole of her nose and cheeks, which took two or three weeks to disappear. I may say I know this ointment as a frequent cause of severe dermatitis. Six years ago she sprained an ankle and applied "white oils," over which she put a dressing. In a short time an acute inflammation of the skin followed, extending up the front of the leg. She also volunteered the statement that some days later the front of the opposite leg, which she had not rubbed, became inflamed over a corresponding area, as she said, "in sympathy." This statement made me hope I should be able to produce a generalised outbreak. I persuaded the patient to come into hospital during her next vacation to undergo the following small experiment under observation:—

Experiment.—May 22nd, 1920, 11 A.M.: Necklace applied round left upper forearm. Bandaged over above and below. Skin at time normal. 8 P.M.: Itching in left forearm; about half an hour later a definite rash; patient slept well. 23rd, 11 A.M.: Punctate red rash forming transverse band about 3 inches wide across flexor surface of left forearm; it reached towards extensor surface on ulnar side, but no actual rash appeared on that surface. The rash became rapidly more irritable and painful during the rest of the day; she could not get to sleep at night, and at 3 A.M. on the 24th she requested that it might be removed on account of the intense discomfort; this was done. 24th, 10.30 A.M.: The affected area had become much wider and was uniformly inflamed, much swollen with numerous vesicles, and very tender and irritable. It now surrounded the arm in a complete ring, but was much wider and more intense on the flexor surface, like a signet ring. Calamine lotion was applied. 25th: Condition more advanced, swelling still acute, more extensive vesiculation running into large blisters and discharging freely. Gauze had been laid over it, and the removal of this caused much discomfort. H.B.F. applied. 26th: Patient slept well; slight itching; less swelling; vesicles less tense. Boric fomentations continued with G.P. tissue. 27th: About 4 P.M. irritation began for about 2 inches above upper edge of original area and extending over hollow of elbow. 28th: The new area is swollen—covered with vesicles. Original rash still very swollen and discharging. At her request lead lotion was applied without any G.P. tissue over it. 29th: The whole area very much better. 30th: She left hospital.

The experiment failed to produce a corresponding eruption in any part distant from the site of application of the irritant although extending much beyond area of contact. Whether it would have done so had the application of the necklace to the already irritated area been persisted in I cannot say, as the patient would not hear of such a thing. It must be admitted that in her case on no previous use of the necklace had there been a generalised outbreak; it had always remained local. There was, however, the history of patches occurring on both legs after applying oils to one only. But the obvious possibility of contact makes this of doubtful value to prove my point.

We have still to explain why this patient developed an acute localised dermatitis when the necklace was laid upon her forearm for a few hours. She has cut the necklace in two and given half to a friend who wears it with impunity. Mechanical friction is no explanation, because the patient wears without any discomfort another necklace made of solid beads. It is unnecessary to consider any internal disorder, for she is in active, robust health and works hard. The trouble must be in the reaction of her skin to this particular type of irritant. I hope that someone may be able to answer the questions I have raised, for I feel that until we have a clearer insight into these simpler reactions of the skin itself it is very difficult to form an estimate of the extent to which they are modified by internal disorders.

ROYAL PORTSMOUTH HOSPITAL.—The sum of £10,000 allocated to the Royal Portsmouth Hospital by the Mayor's War Memorial Fund Committee is to be utilised for erecting a new public entrance to the institution, and also for making several necessary internal alterations.

TWO CASES OF

CONGENITAL HYPERTROPHIC PYLORIC STENOSIS

SAVED BY EARLY OPERATION.

By W. G. MACDONALD, M.B., Ch.B. Glasg.

Congenital hypertrophic pyloric stenosis is generally considered to be a somewhat rare condition; but the frequency with which it is recognised by those who constantly watch for it, establishes the fact that it is relatively common. Since Beardsley, of Connecticut, U.S.A., described the malady there has been much debate concerning its ætiology and treatment. That it is congenital is almost[2] universally believed, although hyperplasia, hypertrophy due to spasm, and fœtal hyperadrenalism have been advanced as probable causes. The pathology has been definitely accepted. There is a hyperplasia of the sphincter pyloris and of the muscularis mucosa of two types: one, the more common, a massive avascular type, and the other, a small, hard, fusiform vascular type. Both are of cartilaginous hardness and constrict the pylorus to a greater or lesser degree. H. Tyrrell Gray and G. R. Pirie[1] show that an inhibition of pancreatic function is associated with the stenosis, a factor which is of great practical importance in the treatment of the disease.

Symptoms usually appear in the third or fourth week, sometimes within a few days of birth and occasionally in the early months of infancy. They are strikingly definite: (1) vomiting (propulsive or projectile type) of all food, (2) constipation, (3) wasting, (4) visible gastric peristalsis, and (5) a palpable pyloric tumour. If the condition is not relieved the child dies of starvation in a few weeks. The differential diagnosis between hypertrophic stenosis and pylorospasm is often difficult; clinical statistics are subject to individual error and unreliable. The presence or absence of a palpable pyloric tumour should decide the diagnosis.

The mortality in cases of congenital hypertrophic pyloric stenosis treated medically is very high.[3] In the United States the condition is regarded as a surgical emergency, and a series of 36 cases since 1905 shows a mortality of 13·8 per cent. Until April, 1918, the surgical mortality at Great Ormond-street Hospital was 100 per cent. Since then operation in "favourable or early" cases in a series of 11 shows a mortality of 9 per cent. In Britain it has been a repetition of the story of the medically treated appendix, with its heavy mortality.

There is a preponderance of evidence to show that the hypertrophic tumour is permanent.[4,7] Cases of stenosis which have been relieved by medical treatment are liable to relapse in later life when intercurrent disease gives rise to a recrudescence of symptoms. But notwithstanding the evidence, physicians of standing recommend that medical treatment should be tried for three weeks or so[6] before surgical measures are taken. Granted that the pyloric tumour is permanent, medical treatment by small predigested feeds, opium and chloral hydrate, and gastric lavage must be a laborious attempt to coax an already dilating stomach to undergo an hypertrophy sufficient to overcome the pyloric stenosis. In moderate degrees of hypertrophic stenosis this may be accomplished, but, as we have seen above, there is a risk of relapse in later life. From the surgical point of view it is astonishing that any infant should be expected to survive the shock of operative treatment after "three weeks or so" of constant vomiting, of starvation, of progressive deterioration of gastric mucosa, and of exhausting stomach lavage. The appalling mortality which follows when surgical treatment is delayed in order to try the effect of medical treatment compares most unfavourably with the light surgical mortality following early operation in the United States and at Great Ormond-street; and this comparison enforces the importance of increasing our knowledge by recording all cases.

The Cases Described.

The following are the first two cases treated at the West Herts Hospital; neither of them could be classified as a good operative risk according to the standards of those who treat congenital hypertrophic stenosis medically, nor could either of them be regarded as a case in which medical treatment was likely to be successfully carried out. There can be little doubt that early operation was the determining factor in their successful issue.

Case 1.—Michael M., born Sept. 4th, 1920, birth-weight 5 lb. His mother had an accidental hæmorrhage on August 19th; she lost a considerable amount and was treated by rest in bed until parturition. The child was jaundiced when born. He began to feed two days later, taking the breast well every two hours during the day and once in the night; seven feeds in 24 hours. The bowels moved each day and the stools were apparently of normal colour and consistence. At the end of the first week, weight had fallen to 4½ lb.; during the second and third weeks the birth-weight was reached though never exceeded.

In the middle of the third week the first evidence of gastro-intestinal trouble appeared, the stools becoming green in colour; and on Sept. 27th, 23 days after birth, projectile vomiting occurred after every feed. Constipation began on the 29th. Olive oil ʒi was given by mouth, and a green, small motion resulted. By the 30th there was absolute constipation, and on Oct. 1st the urine was scanty. The infant was seen by Dr. J. H. Addinsell late on Friday evening, and he found the abdomen distended and very difficult to examine. A saline enema was returned without fæces or flatus. Hot and cold swabs applied alternately to the epigastrium did not precipitate vomiting. Gastric peristalsis was not seen.

On the morning of Oct. 2nd we saw the infant in consultation. He was wizened, wrinkled, jaundiced, and obviously in pain; mouth and eyes were half open; fontanelle sunken; hands clenched; legs flexed on abdomen; abdomen rigid and distended; no visible peristalsis. Vomiting occurred during examination, unchanged food streamed from nose and mouth without apparent effort. The projectile character was lost owing to weakness. On vomiting, the abdominal muscles relaxed and an indistinct tumour was felt behind right rectus in the upper abdomen. The child weighed 4 lb. 6 oz.; his length was 18 inches.

He was admitted to the West Herts Hospital; operation was performed at 2 P.M. on the same day. The abdomen was opened through the upper right rectus. A hypertrophy of pylorus of the large avascular type resembling a decalcified bone bobbin was found. Ramstedt's operation was performed. The sero-muscular coats were split down to mucous membrane in the long axis of the tumour. In doing this the gastric mucosa was inadvertently holed, the wound admitting a fine probe. This wound was closed by one fine catgut suture. Some trouble was met with owing to prolapse of gut, but was fairly easily overcome. The abdomen was closed with three through-and-through sutures. Post-operative shock was combated by warmth, warm moist oxygen, and two-hourly enemata of normal saline ℥i. with glucose ♏ xl.

Case 2.—John D. S., born August 30th, 1920. Birth-weight 8 lb. His mother, a primipara, felt and was well during the whole period of pregnancy; the infant apparently gained in weight for 22 days; but on Sept. 21st he began to vomit after each feed, and on the 22nd vomiting was of projectile type. Constipation began on the 24th, and the bowel did not act until relieved by enema on the 27th, when the district nurse stated that the result was good. On the 30th an enema was given with little result, a few small scybalæ being passed. Projectile vomiting continued. It occurred as soon as food was taken, but occasionally at varying periods up to an hour and a half from the last feed. Glaxo, albumin water, and Allenburys food were tried. Dr. Addinsell, who was called on the morning of Oct. 8th, asked me to see the child with a view to operation.

Examination.—Weight was 6 lb. 7 oz., the length 21 inches. He was emaciated, his legs drawn up on a distended abdomen, his face wrinkled and expressive of pain, fontanelle sunken, skin shrivelled and without elasticity—a typical "Indian famine" picture. No phimosis or preputial adhesions. Visible gastric peristalsis was noted. With the baby lying on the left hand, face downwards, an indistinct tumour to the right of right rectus and under the liver could be palpated. The infant was admitted to the West Herts Hospital at midnight, Oct. 8th. A breast-feed was given and projectile vomiting occurred. Nutrient enemata of normal saline with glucose were given two-hourly until operation. Next morning a quantity of brownish fluid was vomited.

Operation was performed on Oct. 9th. Profiting by our experience in Case 1, a 2-inch incision was made through the upper right rectus exposing the convexity of the liver. On displacing the liver upwards the greatly dilated stomach ballooned through the incision. The pylorus was delivered and found to be of the small hard, fusiform vascular type. The only possible line of incision was along the continuation line of the lesser curvature of the stomach, and it was made by means of knife and blood dissection to normal stomach above and to the well-marked duodenal reduplication of mucosa below. Division of the sero-muscular coats was more difficult to accomplish in this case than in Case 1. The abdomen was closed by three through-and-through silkworm gut sutures.
